The Fourier transform spectrometer generates intensity modulation by varying the optical path difference in a two-beam interferometer. The Fourier transform of the modulated signal yields the spectrum. This technique is capable to reach a very high spectral resolution at a wide spectral coverage, but is interesting also in the case of moderate and low spectral resolving power, because it offers high throughput and compact design. **Figure 4** shows the Fourier transform spectrometer Michelson Interferometer for Passive Atmospheric Sounding (MIPAS)-B, the balloon-borne version of the spectrometer. If the detector noise exceeds the noise associated with the statistics of the incoming photons (most of these may emerge from the instrument itself), the Fourier spectrometer is advantageous over the monochromator, because all spectral elements are measured at the same time. The recent availability of array detectors in connection with increasing data processing capabilities encourages the design of imaging Fourier transform spectrometers. The airborne imaging Fourier spectrometer GLORIA (GLOBal Limb Radiance Imager of the Atmosphere) recorded the first spectra in December 2011. This sensor simultaneously observes 128×128 spectral scenes, covering the $770\text{--}1400\text{ cm}^{-1}$ spectral range at a resolution of 0.1 cm^{-1} .

Fabry–Perot etalons are optical resonators. They combine very high spectral resolution with compact size, but are not in wide use, because the mechanical and optical tolerances are

very demanding, the necessary high reflectivity of the optical resonator is achievable only in quite restricted wavelength regions, and the periodic transmission characteristics makes additional filtering necessary, by either using filters and stages of several etalons, or a predispersing grating.

Gas correlation techniques use the characteristic absorption properties of each gas for its detection: The spectral selection is achieved by a cell filled with the gas under consideration. This cell acts as a highly specific filter for the atmospheric signal. During the measurement, the transmission of the gas probe is modulated by changing the pressure or the path length of the cell. The measured modulation around the average signal level allows to deduce the concentration of the cell gas in the atmosphere. The technique is restricted to a small set of gases with dominating spectral features over a considerable wavelength interval, otherwise it suffers from unacceptable cross-sensitivity to the variability of other species with overlapping spectral features.

In case of the heterodyne detection technique, the signal of a local oscillator is superimposed to the incoming radiation in a mixing element with nonlinear response, a signal oscillating with the beat frequency being generated. The contributions of two symmetrical sidebands above and below the local oscillator are superimposed by this operation, and the undesired sideband can be suppressed by additional filtering before mixing. The signal at the beat frequency is amplified and spectrally analyzed. The technique can reach extremely high spectral resolution, but the spectral coverage is strongly limited. Heterodyne instruments have been realized for frequencies up to the near-IR region.

The Inverse Problem

In remote sensing, the atmospheric variables to be deduced from the measurements are indirectly related to the observed radiances, so an inverse problem has to be solved. Since the radiative transfer in the atmosphere cannot be solved analytically, the analysis relies on the comparison between measured

and computed radiances. A radiative transfer code is required to model the radiances and their derivatives with respect to the wanted variables. The radiative transfer equation (eqn [1]) can be linearized in a vicinity of the current values for the variables, and together with the spectral discretization introduced by the measurement process this allows to apply methods of linear algebra. While the assumption of atmospheric horizontal homogeneity is common in the analysis of spectra, it is not a necessary condition for the radiative transfer modeling and the subsequent inversion. In particular, if the same air volume is probed several times from different positions, a reconstruction of a three-dimensional spatial distribution of variables can be attempted.

The information content of the remote sensing measurement might be insufficient to avoid the propagation of some a priori assumptions on the solution. In some circumstances, the impact of the a priori assumptions on the solution can be profound. If, e.g., the vertical resolution of the remotely sensed measurement is quite poor, it is not permitted to compare the deduced profile with an *in situ* measurement directly. An appropriate smoothing has to be applied to the *in situ* measurement before the intercomparison can be performed.

If the desired variables are not determined by the measurement unambiguously, the solution given by an unconstrained least-squares fit is useless. For illustration, imagine that the elements of the solution vector describe a trace gas profile. If slight changes in the measurement vector lead to tremendous oscillations in the solution vector, the inversion is an ill-posed problem.

Various methods are in use to construct a useful solution: Iterative relaxation methods as the Chahine–Twomey method rely on the fact that oscillatory fine structure in the solution converge more slowly than well-determined broad features. The oscillations in the profile are suppressed by using a finite number of iterations. A truncated singular value decomposition also suppresses unwanted oscillations. The Twomey–Tikhonov method explicitly introduces an additional linear constraint on the solution vector that is weighted vs the fit quality. For example, a smoothness condition on a trace gas profile can be used. Among the most refined inversion methods is the optimal estimation approach: The state of the atmosphere is thought to be represented by an appropriate probability density function. Under the action of the additional spectral information introduced by the measurement, a modified probability density function is generated. The most probable realization of the overall state vector (atmosphere + measurement) might be interpreted as the result of the measurement.

An estimation of errors in remotely sensed data needs an examination of the error mapping from the spectral domain to the set of atmospheric variables deduced from the measurement. To be included into the error budget are the uncertainties of spectroscopic data, the uncertainties of auxiliary atmospheric quantities affecting the spectrum, the impacts of interfering spectral features, instrumental error sources and the impacts of the a priori assumptions. In general, a meaningful error characterization of a remotely sensed set of variables has to take the correlation of errors between the variables into account.

Some Experiments (Past, Present, and Future) and Results

In this section, we present a few examples out of many remarkable remote sensing experiments. The examples are sorted with respect to their platforms, from ground-based to satellite-borne sensors.

Sensors operating in the IR spectral region with sufficiently high spectral resolution can measure more than 30 chemical constituents, as well as temperature. Among these species are O_3 , CO_2 , H_2O , NO , NO_2 , HNO_3 , N_2O_5 , $ClONO_2$, HO_2NO_2 , N_2O , CH_4 , C_2H_6 , SF_6 , CO , $HOCl$, ClO , COF_2 , CFC-11, CFC-12, OCS , H_2CO , and SO_2 . If the experiment relies on the thermal emission of the atmosphere, only the spectral range below approximately 2500 cm^{-1} can be used, therefore some species of interest are not accessible, especially HCl and HF . Due to the limited atmospheric path length as compared to limb sounding, nadir sounding is noticeably less sensitive, and consequently the set of observable species is somewhat limited (H_2O , CH_4 , N_2O , CO_2 , CO , O_3 , HNO_3 , CFC-11, CFC-12, and OCS). The same argument holds for ground-based solar absorption measurements in comparison to tangential absorption measurements.

Sensors operating in the FIR spectral region with sufficient high spectral resolution can measure about 20 chemical constituents including, e.g., O_3 , H_2O , OH , ClO , HCl , HF , HNO_3 , and N_2O .

● Ground-based instruments:

More than 20 ground-based mid-IR Fourier transform spectrometers are operated within the framework of the international organization Network for the Detection of Atmospheric Composition Change (NDACC) at stations all over the world. The spectrometers record solar absorption spectra with about 0.003 cm^{-1} resolution. This is sufficient to resolve the shape of the atmospheric lines. From these spectra, total column amounts of many stratospheric and tropospheric gases, e.g., O_3 , HNO_3 , CO , CH_4 , HCN , and C_2H_6 are deduced. In the case of strong absorbers, such as O_3 and CH_4 , information concerning the vertical concentration profiles can be retrieved in addition.

In Europe, the observations performed by the University of Liege, Belgium, atop the Jungfraujoch ridge document an outstanding tradition in remote atmospheric measurements: Already in 1950, using a grating spectrometer, M. Migeotte inferred the presence of CH_4 and CO from IR absorption features in atmospheric spectra. Since 1975, Fourier transform spectrometers are used for the measurements. Spanning more than three decades in the meantime, the time series deduced from the measurements are well suited for trend analyses. Figure 5 shows trends of several species as deduced from the measurements.

More recently, a second network applying high-resolution ground-based Fourier transform infrared (FTIR) spectrometers has been established. The Total Carbon Column Observing Network performs solar absorption measurements in the near-IR. The oxygen bands observable in this spectral region provide a valuable reference, enabling the measurement of column-averaged dry air mole fractions of greenhouse gases such as CO_2 and CH_4 with unprecedented accuracy.

Figure 5 Trends in inorganic chlorine from 1983 to 2009 as deduced from ground-based FTIR measurements at the high-altitude site Jungfraujoch (Suisse). With kind permission of Demoulin, P. University, Liège.

- Airborne instruments:

The SAFIRE-A (Spectroscopy of the Atmosphere using Far-Infrared Emission-Airborne) instrument is operated on a Russian M-55 aircraft capable of reaching a maximum altitude of 21 km. SAFIRE-A, developed at the Institute of Applied Physics (IFAC) in Florence, Italy, is a Fourier transform spectrometer measuring in the FIR region from 10 to 250 cm⁻¹ with a spectral resolution of 0.004 cm⁻¹ (equivalent to 125 cm max. optical path difference). The interferometer comprises a compact pantographic dual slide design. In the wave number region from 10 to 50 cm⁻¹ bolometers are used, whereas the higher frequency channels are equipped with semiconductor detectors. The main data products of SAFIRE-A are O₃, ClO, HNO₃, and N₂O. On the same airplane, a cryogenic Fourier transform spectrometer for the mid-IR region Michelson Interferometer for Passive Atmospheric Sounding-STR atmospheric aircraft (MIPAS-STR) is operated, that is a descendant of the MIPAS-B experiment (see next paragraph). Precursor instruments of SAFIRE-A have been flown successfully aboard stratospheric balloons.

- Balloon-borne instruments:

The MIPAS-B experiment is a cryogenic limb-sounding Fourier transform spectrometer. The instrument was designed and built by the Institut für Meteorologie und Klimaforschung (IMK) in Karlsruhe, Germany. The flights started in 1989 and, up to now, 23 MIPAS-B flights were performed. The whole instrument is cooled to 195 K, so that the thermal self-emission of the atmosphere can be studied with high spectral resolution. The experiment aims in particular to improve our knowledge of the stratospheric ozone loss by probing the chemical composition of the stratosphere. For the observation of the chemical evolution inside the polar vortex, the independence from solar radiation is especially beneficial. The detector system is equipped with four Si:As Blocked Impurity Band detectors, and allows the simultaneous observations in four spectral channels covering 750–1900 cm⁻¹ with a resolution of 0.033 cm⁻¹ (equivalent to 15 cm max. optical path difference). The first

arctic vertical profiles of the species ClONO₂ and N₂O₅ were provided by this experiment, and the partitioning of chlorine and nitrogen species as well as denitrification events inside the Arctic vortex were studied in some detail. Figure 6 shows the NO_y-budget in the polar vortex, as deduced from MIPAS-B measurements.

The MkIV FTIR spectrometer was designed and built at the Jet Propulsion Laboratory in Pasadena, California, in 1984. The instrument records solar absorption spectra in the entire 700–5700 cm⁻¹ spectral range using two detectors. The resolution is 0.01 cm⁻¹. Vertical profiles of more than 30 species are deduced from sunrise/sunset observations at float height or from balloon ascent/descent measurements. The experiment aims to monitor trace gases in order to test chemical transport models, and to perform correlative measurements for other experiments. The MkIV instrument successfully completed 21 balloon flights since 1989, and has been operated on the NASA DC-8 airplane, too. Moreover, it is used for ground-based measurements in the framework of the NDACC.

The Limb Profile Monitor of the Atmosphere (LPMA) spectrometer operated by the Université Pierre et Marie Curie in Paris, France, follows the same measurement principle as the MkIV instrument. The LPMA experiment demonstrates that a commercial FTIR spectrometer (a Bomem DA-2, offering 0.01 cm⁻¹ spectral resolution) can be successfully operated on a balloon. A balloon instrument for nadir observations has been derived from the LPMA spectrometer, to yield test data for the forward model calculations and the retrieval procedure involved in the Infrared Atmospheric Sounding Interferometer (IASI) satellite experiment.

- Instruments in space:

The ATMOS instrument (Atmospheric Trace Molecule Spectroscopy Experiment) represents the outgrowth of spectrometers developed by the Jet Propulsion Laboratory from 1972 on. The ATMOS sensor itself was designed and built by NASA's contractor Honeywell Electro Optics Center, and was flown four times on the space shuttle in the solar occultation

Figure 6 Profiles of the relevant members of the NO_y chemical family and total NO_y in the nighttime polar vortex as deduced from MIPAS-B measurements. The dotted lines refer to the predictions of the chemical transport model KASIMA.

mode since 1985. More than 30 species have been deduced from the spectra covering the range from 600 to 5000 cm^{-1} with a resolution of 0.01 cm^{-1} . **Figure 7** shows a set of trace gas profiles deduced from ATMOS measurements. Moreover, on the basis of essentially pure solar spectra recorded at high tangent heights, an atlas of the solar spectrum was compiled.

A recent satellite-borne spectrometer with similar characteristics is Atmospheric Chemistry Experiment (ACE), being in

orbit since August 2003. The ACE measurements are extending the ATMOS data set with the advantage of performing observations on a strongly inclined orbit over many years.

The Upper Atmospheric Research Satellite was launched in September 1991 and was in operation until September 2001. Ten instruments yielded a comprehensive suite of geophysical parameters. In the given context, three of these instruments deserve special attention: CLAES is the Cryogenic Limb Array

Figure 7 Trace gas profiles deduced from ATMOS solar occultation spectra during the Spacelab 3 mission in 1985. Note that the range of mixing ratios spans about seven orders of magnitude. The extensive set of species underpins the capabilities of remote sensing in monitoring the chemical composition of the atmosphere. ATMOS data with kind permission of Gunson, M. JPL.

Etalon Spectrometer. The instrument was in operation until May 1993, when the cryogenics used to cool the spectrometer were used up. Among the data products were O_3 , ClONO_2 , N_2O , CH_4 , N_2O_5 , HNO_3 , H_2O , CFCl_3 , and CF_2Cl_2 observed in the spectral range from 780 to 2900 cm^{-1} . ISAMS, the Improved Stratospheric and Mesospheric Sounder, is also a limb sounding radiometer. It used a combination of pressure-modulated and wideband channels in the $600\text{--}2500\text{ cm}^{-1}$ range to perform measurements of the species O_3 , CO , HNO_3 , NO , NO_2 , N_2O , H_2O , and N_2O_5 . ISAMS made measurements from September 1991 to July 1992. HALOE (Halogen Occultation Experiment) also combines wideband and gas cell correlation techniques in the spectral range from $1000\text{ to }4000\text{ cm}^{-1}$. It yielded profiles of the species O_3 , HCl , HF , CH_4 , H_2O , NO , and NO_2 on about 30 available solar occultations each day from October 1991 until November 2005.

The CRISTA experiment (CRYogenic Infrared Spectrometers and Telescopes for the Atmosphere) is a liquid-helium-cooled cryogenic limb scanner. Four grating spectrometers cover the $140\text{--}2500\text{ cm}^{-1}$ region. Three telescopes are used simultaneously to improve the horizontal coverage. The sensor is mounted on the free-flying satellite ASTRO-SPAS that is released and recaptured by the shuttle. Up to now, CRISTA has been in orbit two times, 1994 and 1997. CRISTA measures about 20 species in the $15\text{--}150\text{ km}$ altitude range and is able to observe small-scale dynamical structures due to its good spatial resolution.

The Interferometric Monitor for Greenhouse gases (IMG) experiment was part of the Japanese ADvanced Earth Observing Satellite mission. It was developed by the Japan Resources Observation System Organization for the Ministry of International Trade and Industry. The satellite was launched in August 1996, and was lost in June 1997. The IMG nadir sounder offered a spectral resolution of 0.05 cm^{-1} in the spectral region

from $700\text{ to }3000\text{ cm}^{-1}$. The central aim of IMG was to map global features in the distribution of CH_4 and CO to improve our knowledge on natural as well as anthropogenic sources and sinks of these gases.

The MOPITT (Measurements of Pollution in the Troposphere) instrument on board the Terra satellite was launched in 1999 as part of NASA's Earth observing programme. The project is a collaboration of Canada and the USA. It monitors the global tropospheric concentration of CO using correlation spectroscopy in several spectral channels between $2200\text{ and }4500\text{ cm}^{-1}$.

The MIPAS sensor on board the European Environmental Satellite Envisat is a limb sounder aiming at the composition of the upper troposphere, stratosphere, and mesosphere. It was developed by the European Space Agency and belongs to the core experiments on Envisat, and was originally proposed by H. Fischer and colleagues at IMK (see MIPAS-B entry). Envisat was launched in March 2002 and operated until April 2012. MIPAS uses a dual port interferometer and a dual slide design. The spectral range from $650\text{ to }2400\text{ cm}^{-1}$ is covered by four spectral channels. The spectral resolution is 0.025 cm^{-1} (Figure 8).

The TES (Tropospheric Emission Spectrometer) instrument, built by the Jet Propulsion Laboratory, is designed to examine the troposphere. The Fourier spectrometer TES has been launched aboard Aura (NASA's Earth Observing System) spacecraft in July 2004. TES has both nadir and limb modes of observation, primarily nadir measurements are recorded; the limb mode ($0\text{--}37\text{ km}$ coverage) is only used for special observations. In the nadir mode, the observations will be performed with a spectral resolution of 0.1 cm^{-1} , in the limb mode, a resolution of 0.025 cm^{-1} will be applied. Another innovative feature is the use of focal plane arrays to measure spectra from 16 adjacent directions of view at the same time.

Figure 8 The first Arctic ozone hole as measured by MIPAS in winter 2010/2011, resulting from the prolonged cooling of the Arctic stratosphere. At the same time MIPAS detected elevated concentrations of ClO in the vortex, which proves the conditions for ozone depletion (Sinnhuber et al., 2011. GRL 38, L24814). The left plate shows the ozone volume mixing ratio at 50.0 hPa , the right plate shows the ClO volume mixing ratio at 50.0 hPa measurements taken on 18 March 2011.

Since October 2006 there is a further nadir-looking Fourier spectrometer in orbit. The IASI instrument observes the spectrum between 3.6 and 15.5 μm from a low-altitude sun-synchronous orbit, covering a swath width of 2000 km. The mission objectives are to provide information on temperature, water vapor, and ozone profiles, as well as fractional cloud cover and cloud top temperature. In addition, IASI can also quantify total or partial columns of other atmospheric species as CH_4 , CO , N_2O , HNO_3 , CFCs, and OCS.

Observations for Chemistry (Remote Sensing): Lidar

G Vaughan, University of Manchester, Manchester, UK

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

The applications of lidar to remote sensing of atmospheric composition are very diverse. Atmospheric particles (aerosols, clouds, and volcanic ash) are readily detected and the altitude of layers is accurately measured, while depolarization provides a means for distinguishing liquid droplets (spherical) from solid particles (irregular). For gaseous composition, two methods are commonly used – Raman scattering and differential absorption, the latter of which has the widest application. Ozone, humidity, and boundary-layer pollutants are commonly measured by lidar from many stations worldwide. Mesospheric metals and radicals may also be measured by resonance fluorescence.

Introduction

This article illustrates applications of lidar to studies of atmospheric chemistry and physics through measurement of trace atmospheric constituents. The fundamentals of lidar, and the different techniques that it can exploit (Rayleigh, Mie, and Raman scattering, differential absorption, Doppler and resonance scattering) are described in articles **Lidar: Atmospheric Sounding** Introduction; Backscatter; Differential Absorption Lidar; Doppler; Raman; Resonance of this Encyclopedia and are not repeated here; the reader is advised to consult those articles if unfamiliar with the lidar technique.

Lidar has a particular strength for atmospheric measurement in its ability to combine the high resolution of *in situ* measurements with the coverage (in space and time) of passive remote sensing. A vertically pointing lidar can measure humidity (for instance) with a vertical resolution of a few tens of meters, and, if atmospheric conditions allow, provide continuous measurements over a period of many hours. An airborne ozone lidar has a lower vertical resolution (a few hundred meters) but will measure a curtain of ozone values ~10 km deep and hundreds or thousands of kilometers long during a typical flight. Such measurements have been crucial in advancing our understanding of the interaction between atmospheric chemistry and dynamics. At the present time, space-borne lidars are being developed, which will extend the benefit of lidar to global measurement, vastly improving the vertical resolution attainable with passive remote sensing techniques, particularly in nadir sounding.

Lidars designed for measurements above the planetary boundary layer usually point only in the vertical direction. In this part of the atmosphere, vertical gradients greatly exceed horizontal gradients and there is no advantage in a scanning capability. For many boundary-layer applications however there is a need to scan the laser beam through a range of zenith angles and azimuths. This is particularly acute for measurements near sources – e.g., monitoring of hydrocarbon emissions from oil refineries or methane leaks from gas pipelines. Some of the most important commercial applications of lidar relate to such problems and to the general issue of pollutant dispersion, so scanning lidar technology is well established in industry. For scientific applications, however, the majority of lidar observations of composition have used a vertically pointing beam.

Aerosol Observations

Aerosols are tiny liquid or solid particles (usually less than 1 µm in diameter) suspended in the atmosphere. They play an important role in nucleating clouds (and so affect climate) and in high concentrations they impact on air quality. The lidar technique is readily applied to aerosol observations since the aerosols provide a direct backscatter signal. This can either be used by itself or converted to the lidar backscatter ratio, R :

$$R = \frac{\text{measured backscattered signal}}{\text{backscattered signal from air alone}}$$

The aerosol-free backscatter can either be measured using rotational or vibrational Raman scattering from atmospheric N₂, or calculated from a coincident temperature profile measured (for instance) by a radiosonde.

One important application of this technique has been in the monitoring of stratospheric aerosol during volcanically perturbed periods (**Figure 1**). Regular lidar observations of stratospheric aerosols began in the late 1970s and have continued until the present day. An example, showing integrated backscatter measured at Garmisch-Partenkirchen (47.5° N, 11° E) is shown in **Figure 2**, and clearly demonstrates the massive perturbations to stratospheric aerosol caused by the eruptions of El Chichon (1983) and Mt Pinatubo (1991), as well as a string of minor perturbations from smaller eruptions. Although the global-scale evolution of the aerosol cloud is best observed from satellites, the ability of lidar to resolve small-scale features and to measure correctly at the lowest levels in the stratosphere makes it an invaluable tool, especially during the early phase of a volcanic event. In the troposphere and lowermost stratosphere volcanic ash presents a hazard to aviation, and it is imperative that the height as well as horizontal extent of an ash cloud be accurately tracked. In 2010, for example, lidar measurements proved invaluable for tracking the ash cloud of the Eyjafjallajökull volcano in Iceland, which caused extensive disruption to air traffic over Europe.

A single laser wavelength is sufficient to monitor volcanic events, but information on the size distribution and composition of aerosols requires multiwavelength lidars. Even with wavelengths spanning the infrared and UV from 300 to 2000 nm, the problem is under-constrained, and modeled theoretical shapes for the size distribution (e.g., lognormal)

Figure 1 Lidar backscatter ratio profile at 532 nm measured at Aberystwyth, Wales (52.4° N, 4° W) on 27 January 1992, showing stratospheric aerosol caused by the eruption of Mt Pinatubo in June 1991.

must be assumed. Nevertheless, multiwavelength lidars combined with theoretical modeling provide valuable constraints on the properties of stratospheric aerosols.

Further information on the phase of aerosols may be gained by measuring the depolarization of the lidar signal. The laser

beam is usually plane polarized, and atmospheric gases and spherical droplets depolarize either very weakly or not at all. Solid particles, however, depolarize strongly. An important application of this technique to atmospheric chemistry has been in the study of polar stratospheric clouds (PSCs). PSCs come in two forms – ice clouds (PSC type 2), which strongly backscatter and depolarize the laser beam, and non-ice clouds (PSC type 1), which are much smaller, weakly backscattering particles. Based on lidar observations these are further divided into type 1a particles, which depolarize the laser beam, and type 1b particles, which do not. The latter are interpreted as supercooled ternary solutions (liquid droplets) of nitric acid, sulfuric acid, and water, and the former as crystalline nitric acid trihydrate. The distinction is important for atmospheric chemistry since the rates of heterogeneous reactions releasing chlorine are different for the different type 1 PSCs, as is their sedimentation velocity: the type 1b particles are significantly smaller than the type 1a particles. (See the articles on stratospheric composition for further information on the importance of chlorine for ozone destruction). Lidar has played a pivotal role in building this picture of PSC composition and the way in which one type can evolve into another, for instance in a mountain wave.

In the boundary layer, the aerosol population can have a very complex distribution of sizes and composition; this is particularly true for polluted air masses. In such cases the lidar backscatter ratio is difficult to interpret scientifically, and extensive ancillary information is needed to derive, for instance, the aerosol scattering coefficient. For this application, extinction of the laser beam is a more useful measurement. This can be readily accomplished from the N₂ Raman-shifted backscatter, where the signal is from the air alone but the extinction results from both air and aerosol scattering. Currently, the EARLINET network of 28 stations in Europe routinely monitor boundary-layer aerosol by measurements of

Figure 2 Integrated aerosol backscatter (vertically integrated profile of R-1) at 694.3 nm, measured by lidar at Garmisch-Partenkirchen (47.5° N, 11.1° E) since 1976. Figure courtesy of T. Trickl, IMK-IFU, Karlsruhe, Germany.

backscatter and extinction, building up a climatology of its vertical distribution.

Ozone Observations

One of the main applications of the lidar technique to atmospheric chemistry has been in observations of ozone. Ozone absorbs strongly in the ultraviolet part of the spectrum, and furthermore the absorption coefficient varies rapidly with wavelength. These two facts make the differential absorption (DIAL) method ideal for ozone measurements. The exact choice of wavelengths used in an ozone lidar depends on the atmospheric region to be probed: troposphere or stratosphere. Ozone concentrations in the troposphere are usually less than 150 ppbv, so lidars can operate in the solar-blind region (<300 nm), where the stratospheric ozone layer completely absorbs the sun's radiation. This means that background light levels are very low even in daytime, enabling 24-h lidar operation without sophisticated wavelength selection in the receiver. For stratospheric observations, returns are needed from above the ozone concentration peak, so these lidars must use wavelengths above 300 nm and are not solar-blind.

Most existing ozone lidars use either Nd-YAG or excimer lasers. The fourth harmonic of the Nd-YAG at 266 nm may be used for boundary-layer measurements (typically, three or more wavelengths are needed for accuracy in the boundary layer because of interference by aerosols), but is absorbed too quickly for measurements more than ~ 2 km above the lidar. Stimulated Raman scattering, however, can be used to convert the laser to longer wavelengths, which can cover the entire troposphere – e.g., 289 nm (first Stokes line of deuteride (D_2)), 294 nm (hydrogen deuteride (HD)), and 299 nm (hydrogen (H_2)). The advantages of cost, ease of use, and wavelength stability mean that Nd-YAG lasers are widely exploited for tropospheric ozone lidars.

Excimer lasers have considerable advantages as lidar transmitters, being very bright and with a high pulse repetition frequency. The XeCl laser, with its wavelength of 308 nm, is ideal for stratospheric ozone measurements and is extensively used in ground-based ozone monitoring. The second DIAL wavelength may be provided by another laser (e.g., a third harmonic Nd-YAG at 355 nm), by stimulated Raman scattering from the main laser beam (e.g., 353 nm using H_2) or by using back-scattered Raman-shifted radiation from atmospheric N_2 at 332 nm. Because of the substantial difference between the two wavelengths these configurations are subject to aerosol interference, particularly in volcanically perturbed conditions, which introduces substantial systematic error. One solution to this problem is to use only Raman-shifted backscatter for the DIAL wavelengths – e.g., 332 and 387 nm (the N_2 Raman-shifted wavelength from 355 nm): such a configuration also allows ozone retrieval in PSCs. However, when the stratospheric aerosol concentration is near to background levels, such sophistication is not necessary and a simple two-laser DIAL lidar is sufficient.

There have been a number of intercomparisons between XeCl stratospheric ozone lidars and other techniques such as electrochemical ozonesondes, ground-based microwave, and satellite instruments. Agreement is best between 20 and 30 km, where $\pm 5\%$ between different lidars, and between

lidar and sonde may be expected. Above 30 km the sondes are unreliable and below 20 km systematic errors in the lidars become more apparent. The accuracy of a DIAL lidar tends to be limited by precision at higher levels (typically determined by the photon count rate) and systematic effects such as overloading of the photo multiplier detectors at lower levels. Agreement between different XeCl lidars, and between lidars and ozonesondes, is generally around 10% between the tropopause and 20 km.

Lidars designed to measure in the troposphere and the lowermost stratosphere normally use wavelengths closer together than stratospheric lidars: e.g., the 289/299 nm pair obtained from an Nd-YAG laser, by stimulated Raman scattering. These lidars generally agree with other techniques (ozonesondes, aircraft-borne UV spectrometers) to better than 10%, and are less susceptible to aerosol interference than their stratospheric counterparts. Very high aerosol concentrations in the planetary boundary layer do present a problem, however, and a lidar with three or more wavelengths is needed for accurate ozone measurements in such conditions. In the lowermost stratosphere, under background aerosol conditions, a DIAL wavelength pair such as 299 and 316 nm (the latter is the second Stokes line from the Raman scattering of 266 nm by D_2) can measure profiles with an accuracy better than 5%.

Because of the accuracy and inherently good vertical resolution of the lidar technique, ozone lidars are well suited for routine monitoring of the ozone layer and for validation of satellite measurements. In the troposphere and lower stratosphere the ability to make continuous measurements over time confers an extra advantage. Ozone in this part of the atmosphere is generally considered a tracer, in other words changes in its concentration at a particular location are due to transport rather than chemistry. The distribution of ozone is intimately linked to weather systems, and measurement of the ozone distribution gives an immediate picture of the effect of weather systems on transport in the atmosphere. One of the most successful applications of tropospheric ozone lidars has been in studies of stratosphere–troposphere exchange. Stratospheric ozone concentrations are many times higher than in the troposphere, and a layer of stratospheric air drawn into the troposphere is readily detected by lidars. Furthermore, as the layer advects over the lidar site, its horizontal structure is revealed. An important example is the tropopause fold, a layer of stratospheric air extruded down into the frontal zone beneath a jet stream. The converse – layers of tropospheric air transported into the lower stratosphere by breaking Rossby waves – are also readily detected by lidar.

These advantages of temporal continuity and vertical resolution are exploited to the full in airborne lidars. Rather than wait for the atmosphere to bring an interesting event to a stationary lidar, an aircraft takes the instrument to the event, and has become a standard tool for studies of stratosphere–troposphere exchange and long-range transport of pollution. A cross section of a tropopause fold measured by an airborne lidar is shown in [Figure 3](#); it clearly depicts the morphology and scale of this event. Equally valuable is the ability of a downward-pointing lidar to map out the extent of a pollution plume, either from an individual city or in the outflow from a continent to a nearby oceanic region. An example is shown in [Figure 4](#).

Figure 3 Tropopause folds revealed by airborne ozone lidar on 25 June 1996 over Brittany and the Bay of Biscay, as layers of high ozone sloping downward into the troposphere. Figure courtesy of G. Ancellet, Service d'Aéronomie, Paris.

Humidity Observations

Accurate measurements of atmospheric water vapor, especially in the dry, cold air of the upper troposphere and stratosphere, are notoriously difficult. Two lidar techniques may be used to measure water vapor, which provide a valuable source of observations in their own right and for intercomparison with other techniques.

The most direct measurement of water vapor is by Raman scattering. The vibrational Raman spectrum of a particular molecule provides a unique spectral signature, so that by spectrally analyzing the backscattered radiation from a vertically pointing laser beam the composition of the atmosphere may in principle be determined. In practice the scattering from most minor constituents is too weak to be detected, or is masked by returns from O_2 and N_2 . The two important exceptions are methane (see below) and water vapor. The first vibrational Raman line of water vapor, at 3652 cm^{-1} , is well separated from O_2 at 1556 cm^{-1} and N_2 at 2331 nm^{-1} . The ratio of backscattered intensity from H_2O and N_2 should give a direct measurement of humidity mixing ratio unaffected by aerosol and by most systematic errors in the lidar (e.g., alignment). This is particularly attractive for a reference instrument – it turns out that the largest source of systematic error in a Raman humidity lidar is inadequate knowledge of the scattering cross sections of H_2O and N_2 . An example of a lidar humidity profile compared with a nearby radiosonde is shown

in Figure 5. Long integration times are required to obtain good measurement precision in the upper troposphere.

Vibrational Raman scattering is very weak – thousand times weaker than Rayleigh scattering. A Raman lidar therefore needs a powerful laser and large collecting optics, as well as excellent wavelength selection to avoid interference by elastically scattered and background light. However, a Raman lidar does have a major advantage for ground-based operation: the weak scattering means there is no problem observing the very dry upper troposphere through the relatively moist lower layers. This sharp decrease with altitude of atmospheric humidity militates against the DIAL technique for ground-based profiling. For aircraft lidars, however the situation is reversed – the aircraft can look down through progressively more humid layers. Greater absorption of the laser signal with depth compensates for the reduced signal-to-noise ratio, so ensuring accurate measurements over a range of many kilometers with one wavelength pair. This, together with the high-powered lasers and large collecting optics required for Raman lidars, makes DIAL the favored technique for airborne lidars. Observations in the 730, 815, and 940 nm absorption bands (using alexandrite, Ti:sapphire, and optical parametric amplifier lasers, respectively) have all been made from research aircraft, together covering the entire troposphere and lower stratosphere up to about 17 km. These observations have similar applications to those of airborne ozone lidars – e.g., studying the extent and evolution of tropospheric haze layers and the

Figure 4 Cross section of ozone concentration in ppbv measured with NOAA/ETL's airborne ozone lidar during the 1995 Southern Oxidants Study field campaign in the Nashville, Tennessee area. The data were taken on 12 July 1995 during a flight leg extending from the northwest to the southeast of Nashville. Note the region of high ozone concentrations over the Nashville urban area indicated by the red and black colors. Figure courtesy of R. Alvarez, NOAA Environmental Technology Laboratory, Boulder, CO 80305, USA.

structure of streamers of low-latitude air in the lower stratosphere.

Pollutant Measurements in the Boundary Layer

One of the most important applications of lidar lies in its ability to make remote measurements of pollutant emissions from industrial sources. In the modern regulatory environment such a capability is of great commercial value, and many lidar systems have been developed around the world to provide it. Typically, such a lidar is mounted in a truck or van and driven to the perimeter of the site under investigation. The lidar performs a two-dimensional scan of the region upwind and downwind of the emission source, mapping the pollutant concentration as a function of height and elevation angle. When combined with coincident wind measurements (e.g., from a meteorological tower), the flux of pollutant being emitted from the site may be estimated. The lidar's ability to make range-resolved measurements makes

it the primary tool for remote sensing investigations of this type.

Early applications of lidar to pollutant monitoring used the Raman technique. Raman has the advantage that it does not require a specific laser wavelength, but it has two main disadvantages as already mentioned: Raman backscatter is very weak, and the rotational-vibrational bands of O_2 and N_2 can mask Raman lines from minor constituents. An advantage of Raman is that good range resolution can be achieved if the back-scattered signal is sufficiently large. A typical application of the Raman technique has been to search for leaks from gas pipelines – concentrations of $\sim 1\%$ methane may readily be detected 1 km away.

Recent work in this field, however, has almost exclusively exploited the DIAL technique. As new and better tunable laser transmitters are developed – especially in the infrared – new applications for DIAL are opened up. The two wavelength regions most commonly exploited are the ultraviolet between 230 and 300 nm, and the infrared between 3 and 5 μm . In the former, gases such as nitric oxide (226 nm),

Figure 5 Humidity profile measured by Raman lidar at Aberystwyth, Wales (52.4° N, 4° W) on 19 October 1999, compared with a radiosonde (Vaisala RS80) launched from Aberporth (42 km away) at 2330 h. The lidar profile is an average of four hours' data. Error bars on lidar profile denote 1 standard deviation. Radiosonde profile provided by UK Met Office.

sulfur dioxide (287 nm), toluene (267 nm), and benzene (253 nm) have sharp absorption lines making them suitable for DIAL detection: this spectral region is also solar-blind, with obvious advantages for daytime operation. Dye lasers,

pumped by Nd-YAG and frequency-doubled Dye lasers, pumped by Nd-YAG, were used in many early lidars of this type, but the advent of tunable solid-state lasers such as Ti:sapphire has led to more powerful and compact transmitters. Closely related to these lidars is the NO_2 lidar, typically operating near 450 nm, which is used to detect the emission of this gas from combustion sources.

Another gas that can be detected readily by UV lidar is mercury vapor. Mercury is released from its ore, cinnabar, by roasting it, and in regions where this extraction is practised (particularly the huge cinnabar deposits at Almadén in Spain), there is an obvious concern about the poisonous effects of mercury vapor. Since mercury has a very strong electronic transition at 253.6 nm it is readily detected (in high enough concentration) by DIAL lidar, and indeed much work has been conducted at Almadén on the dispersion of mercury vapor using DIAL.

The advent of high-quality infrared nonlinear optical materials has led to a new class of bright, stable infrared laser beams, usually obtained through nonlinear mixing of Nd-YAG and dye lasers. These infrared sources are tunable and have very narrow line widths (0.1 nm is attainable), opening up the possibility of DIAL measurements in the infrared. Very many molecules of atmospheric interest have vibrational-rotational bands in the near infrared (2–5 μm), and provided that interference with water vapor and CO_2 bands can be avoided, they can be measured with infrared DIALs. Examples are methane (CH_4), acetylene (C_2H_2), ethylene (C_2H_4), and ethane (C_2H_6). The obvious application for such lidars is to measure emissions from petrochemical plants and storage facilities, although they are also useful for tracking plumes for several kilometers downwind of industrial sources.

An example of a mobile lidar designed for pollution measurements is that operated by the UK's National Physical Laboratory, London (Figure 6). This uses an Nd-YAG-pumped dye laser for UV measurements via a second harmonic generator and for IR measurements via a LiNbO_3 difference frequency meter. The gases measurable with this technique

Table 1 Typical parameters of the National Physical Laboratory DIAL lidar system

Species	Laser wavelength	Measurement sensitivity at 200-m range, ppbv
Nitric oxide, NO	226 nm	5
Nitrogen dioxide, NO ₂	450 nm	10
Sulfur dioxide, SO ₂	300 nm	10
Ozone, O ₃	289 nm	5
Mercury vapor, Hg	254 nm	0.5
Benzene, C ₆ H ₆	253 nm	10
Toluene, C ₇ H ₈	267 nm	10
Methane, CH ₄	3.42 μm	50
Ethane, C ₂ H ₆	3.36 μm	20
Ethylene, C ₂ H ₄	3.35 μm	10
Acetylene, C ₂ H ₂	3.02 μm	40
Hydrogen chloride, HCl	3.42 μm	20
Nitrous oxide, N ₂ O	2.90 μm	100
Methanol, CH ₃ OH	3.52 μm	200

(together with their typical detection limits for a 100-m diameter plume centered at 200 m range) are shown in Table 1. A 12-m mast carries wind, temperature, and humidity sensors, used to convert the number density to mixing ratio and to calculate fluxes across the plane scanned by the lidar. The system is calibrated by reference to standard cells with known concentrations of the measured gases. It has been used to measure volatile organic compound emissions from more than 20 different petrochemical facilities, including oil refineries, retail petrol stations, and an ethylene processing plant, and also for methane emissions from landfill.

Mesospheric Chemistry

The most distinctive aspect of mesospheric chemistry to be studied by the lidar is that of metal atoms and ions of meteoric origin (*see Mesosphere: Atomic Species in the Mesopause Region; Metal Layers; Polar Summer Mesopause. Solar System/Sun, Atmospheres, Evolution of Atmospheres: Meteors*). Meteors ablate in the 90- to 100-km altitude range, releasing their contents as vapors. Metal atoms and ions are characterized by excited electronic states with excitation energies corresponding to visible photon wavelengths. Such is the low density in the upper mesosphere (~ 0.01 Pa) that collisional quenching of these states is generally much slower than their radiative decay. Under these conditions resonance scattering comes into its own as a lidar technique: if the laser beam is tuned to an electronic transition of the desired species, the backscatter cross section is enhanced by an enormous factor – typically of order 10^{16} . This enables concentrations of metal atoms or ions as low as 10^7 m⁻³ to be measured by lidar.

The first and most extensively studied species to be measured in this way was sodium, using the D₂ line at 589 nm. Profiles have also been measured of potassium (770 nm), lithium (671 nm), neutral and ionized calcium (423 and 393 nm, respectively), and iron (372 nm). The altitude distribution of these species corresponds to the meteor ablation region, with a peak concentration at ~ 90 km. In the case of sodium the measured concentrations vary strongly with season

and latitude, being greatest in winter and at high latitudes. A typical sodium atom concentration at 90 km at 69° N is around 5×10^9 m⁻³. Surprisingly, the strong seasonal variation characteristic of sodium is not found for potassium, which changes little over the year. All the metals so far studied exhibit thin layers of greatly enhanced concentration, which appear sporadically and last typically a few hours. Their origin remains something of a mystery, as does their distribution – enhanced sodium layers, for instance, are found mainly at low and high latitudes, whereas iron layers are commonest in midlatitudes. There is also some uncertainty about the relative concentration of different metals. Whereas those of sodium, potassium, and lithium are consistent with their meteoric source, the concentrations of iron and calcium are much lower than expectation. The advent of tunable solid-state lasers promises to simplify considerably the construction of lidars for mesospheric metal measurements, so that rapid advances in this field may be expected in the next few years.

Also measured in the mesosphere by lidar is the hydroxyl radical, OH. In fact this measurement is a serendipitous bonus of stratospheric ozone lidars based on XeCl lasers. The 308-nm laser wavelength falls within an electronic excitation band of OH, which means that resonance scattering is possible, as for metal atoms (although the technique is often called laser-induced fluorescence there is no wavelength shift between transmitted and received radiation). A layer of enhanced backscatter appears at night between 75 and 85 km at 308 nm, corresponding to OH concentrations of $2\text{--}4 \times 10^5$ radicals cm⁻³. The existence around the world of several lidars for stratospheric ozone monitoring means that the temporal and latitudinal variation of mesospheric OH may be followed for little extra cost.

Introduction

Microwave remote sensing observations for atmospheric chemistry have been obtained from ground, aircraft, balloon, and satellite platforms. Examples of results are given later in this article, after describing the measurement fundamentals, chemical species having microwave spectra, and instrumentation. The technique has been used, to date, for observations of stratospheric and mesospheric chemistry. It has not yet been applied to tropospheric chemistry, primarily because of difficulties associated with tropospheric H₂O absorption and the larger widths of tropospheric spectral lines. Recent technological advances have removed the second difficulty, and future application to the *upper* troposphere, where there are sufficient spectral windows, is expected. Microwave observations of chemical species can be made in the presence of clouds and volcanic aerosols that limit shorter-wavelength infrared, visible, and ultraviolet techniques.

'Microwave' is used here to denote heterodyne measurements at centimeter, millimeter, and submillimeter wavelengths. The spectral range of interest extends, roughly, from the 1.35 cm wavelength (22 GHz frequency, 1 GHz = 10⁹ Hz) H₂O spectral line through the 0.12 mm wavelength (2.5 THz frequency, 1 THz = 10¹² Hz) OH lines. 'Heterodyne' indicates multiplying a weak input signal by a strong local oscillator signal to translate – without loss of information – the input signal to a portion of the spectrum more convenient for further processing. This process allows measurements of weaker signals, and better spectral resolution, than can generally be obtained with other techniques. Technology for low-noise submillimeter heterodyne measurements has become available only recently, and is advancing rapidly. Far-infrared non-heterodyne techniques made the first measurements of the atmospheric submillimeter spectrum.

Resolved spectral lines providing unique signatures of selected species are measured. Measurements can be either of atmospheric thermal emission or of absorption against a source such as the Sun; most are of thermal emission in order to obtain results at all times of day and night. Temperature is usually obtained from emission by O₂ but can also be obtained from other gases. The rotational states usually sensed are in thermal equilibrium well up through the mesosphere, easing interpretation. The approximately linear temperature dependence of the Planck function at the observed wavelengths and temperatures means that uncertainties in atmospheric temperature generally do not limit accuracy of the measured abundance. The resolved line measurements give robust results: taking the difference between outputs from nearby channels 'on' and 'off' a line can eliminate artifacts while retaining the signal. The 'shape' of output from channels covering the line, which must have a certain form, also provides robustness and information on the altitude profile. Mathematical techniques

for retrieving abundance and temperature from remote measurements are well established.

Figure 1 shows the tropospheric spectrum for the wavelength region considered here. The window at ~200–300 GHz is especially productive for ground-based measurements of stratospheric chemistry. Aircraft, balloon, and satellite platforms usually must be employed for measurements above ~300 GHz owing to tropospheric H₂O absorption.

Measurement Fundamentals

The power in the atmospheric signal measured at frequency ν over incremental range $d\nu$ can be written as eqn [1].

$$dP_\nu = \frac{1}{2} d\nu \int_{\Omega} I_\nu(\theta, \phi) A_e(\theta, \phi) d\Omega \quad [1]$$

$I_\nu(\theta, \phi)$ is the intensity (W Hz⁻¹ m⁻² sr⁻¹) of atmospheric radiation from direction (θ, ϕ) and $A_e(\theta, \phi)$ is the instrument's effective collecting area in that direction. The integration is over all solid angle Ω ; the factor 1/2 appears because only one polarization is received and random polarization is assumed here for the atmospheric radiation. The collecting area of a heterodyne 'radiometer' (instrument for measuring radiative power) has the property [2], where $\lambda = c/\nu$ is the wavelength of the radiation ($c = 2.998 \times 10^8$ m s⁻¹ is the speed of light), and is related to $G(\theta, \phi)$, the instrument's 'antenna gain pattern', by $A_e(\theta, \phi) = \lambda^2 G(\theta, \phi)/4\pi$.

$$\int_{\Omega} A_e(\theta, \phi) d\Omega = \lambda^2 \quad [2]$$

Equation [2] has important practical implications: the instrument's collecting area integrated over solid angle is just the square of the wavelength, independent of its 'physical' size. The power collected from a source that fills the antenna beam, generally true for atmospheric measurements, is not increased by increasing the aperture's physical size. The increase in power that might have been expected from the aperture size increase is, owing to diffraction effects, offset by a decrease in the angular range over which radiation is collected. The instrument field-of-view (FOV) width (in radians) in a particular plane is, approximately, the inverse of the aperture dimension (in wavelengths) in that plane. Because the integrated collecting area is λ^2 , the power per unit frequency interval collected at frequency ν from blackbody radiation is $\frac{1}{2}\lambda^2 B_\nu(T)$, where $B_\nu(T) = (2h\nu^3/c^2)/(e^{h\nu/kT} - 1)$ is the Planck function giving the radiation intensity; $h = 6.626 \times 10^{-34}$ Js is the Planck constant; and $k = 1.38 \times 10^{-23}$ W Hz⁻¹ K⁻¹ is the Boltzmann constant. For temperatures in Earth's atmosphere, $\frac{1}{2}\lambda^2 B_\nu(T)$ is nearly constant with ν up to ~5 THz, beyond which it drops rapidly, as shown in Figure 2. Heterodyne measurements of atmospheric thermal emission are, thus, relatively efficient at

Figure 1 Atmospheric zenith transmission above a 4 km high mountain (a) and above an aircraft at 12 km (b). The absorption features seen here are due to H₂O and, to a lesser extent, O₂. Reproduced with permission from Phillips TG and Keene J (1992) Submillimeter astronomy. Proceedings of the IEEE 80: 1662–1678. © 1992 Institute of Electrical and Electronics Engineers, Inc.

frequencies up to $\sim 5\text{THz}$ ($\lambda > \sim 5 \times 10^{-5}\text{m}$), but not much beyond. Shorter-wavelength (e.g., infrared) heterodyne atmospheric measurements are usually made of solar absorption.

The intensity of radiation from a given direction is given by eqn [3].

$$I_\nu = I_\nu(0)e^{-\tau_\nu(0,L)} + \int_0^{\tau_\nu(0,L)} B_\nu(T)e^{-\tau_\nu(s,L)} d\tau_\nu(s) \quad [3]$$

Figure 2 The power per unit frequency interval collected by a heterodyne instrument at frequency ν from a blackbody radiation field at 200 and 250K. The function is plotted in units of W MHz^{-1} , as MHz is the typical unit for widths of microwave spectral lines. Reproduced with permission from Waters JW (1993) Microwave limb sounding. Chapter 8 in Janssen MA (ed.). Atmospheric Remote Sensing by Microwave Radiometry. New York: Wiley. © 1993 John Wiley.

The integral is over the radiation path through the atmosphere with the instrument at L , $I_\nu(0)$ is the radiation at point 0 outside the atmosphere and τ_ν , given by eqn [4], is the 'optical depth' at frequency ν between points s and L on the path, where $\alpha_\nu(s)$ is the 'absorption coefficient' (having dimension 1/length) at s .

$$\tau_\nu(s,L) = \int_s^L \alpha_\nu(s) ds \quad [4]$$

Combining eqns [1], [2] and [3], the power collected from a thermal emission signal (no $I_\nu(0)$ term in eqn [3]) over frequency range $\Delta\nu$ can be written as eqn [5].

$$P_{\text{sig}} = \frac{\lambda^2}{2} \overline{B_\nu(T)} (1 - e^{-\tau_\nu(0,L)}) \Delta\nu \xrightarrow{\tau_\nu(0,L) \ll 1} \frac{\lambda^2}{2} \overline{B_\nu(T)} \tau_\nu(0,L) \Delta\nu \quad [5]$$

In eqn [5] an overbar indicates an appropriate average, and the rightmost expression applies to signals with small optical depth. The microwave signal power is usually expressed as signal 'brightness temperature'. This quantity is proportional to the detected power from the signal, has units of temperature, and for $h\nu \ll kT$ converges to the temperature of blackbody radiation that would give rise to the amount of detected power from the signal (eqn [6] where eqn [5] has been used to obtain the expression for large optical depth after the first arrow).

$$T_{\text{sig}} \equiv \frac{P_{\text{sig}}}{k\Delta\nu} \xrightarrow{\tau_\nu(0,L) \gg 1} \frac{\lambda^2}{2k} \overline{B_\nu(T)} \xrightarrow{h\nu \ll kT} \bar{T} \quad [6]$$

The absorption coefficient for an isolated spectral line is given by eqn [7].

$$\alpha_v^{ul} = n \frac{2\pi^2 g_l \phi_{ul}^2 \mu^2}{3\epsilon_0 h c Q(T)} \times [e^{-E_l/kT} - e^{-E_u/kT}] v b(v, \nu_{ul}) \quad [7]$$

In eqn [7] n is number density of the species with the spectral line, u and l denote the upper and lower quantum states involved in the transition, g_l is the degeneracy and E_l the energy for state l , ϕ_{ul}^2 is the transition matrix element (sometimes g_u is included in ϕ_{ul}^2), μ is the overall dipole (or other) moment coupling to the radiation field, and $\epsilon_0 = 8.854 \times 10^{-12} \text{ F m}^{-1}$ is the permittivity of vacuum. $Q(T) = \sum_{g_l} \exp(-E_l/kT)$ is the partition function, and it is assumed that the quantum states are in thermal equilibrium. The 'line shape function' $b(v, \nu_{ul})$, normalized such that $\int b(v, \nu_{ul}) dv = 1$, gives the probability density that the transition is observed at frequency ν rather than the nominal $\nu_{ul} = (E_u - E_l)/h$.

Atmospheric microwave line shapes are dominated by collision (pressure) broadening at lower altitudes and Doppler (thermal motion) broadening at higher altitudes. The collision linewidth parameter (half-width at half-maximum) can be written $\Delta\nu_c^{ul} = (\Delta\nu_{co}^{ul}) \cdot (\rho/1 \text{ hPa}) \cdot (T/300 \text{ K})^{-x}$ where ρ is atmospheric pressure, and $\Delta\nu_{co}^{ul}$ and x are constants. Typical values are $\Delta\nu_{co}^{ul} = 2.5 \text{ MHz}$, $x = 0.75$. The Lorentz shape, $b(v, \nu_{ul}) = [\Delta\nu_c^{ul}/\pi] / [(v - \nu_{ul})^2 + (\Delta\nu_c^{ul})^2]$, is applicable to the narrow collision-broadened lines measured for atmospheric chemistry. Doppler broadening gives a Gaussian shape $b(v, \nu_{ul}) = (1/\Delta\nu_D^{ul}) (\ln 2/\pi)^{1/2} \exp\{-\ln 2[(v - \nu_{ul})/(\Delta\nu_D^{ul})]^2\}$ with linewidth parameter $\Delta\nu_D^{ul} = (\nu_{ul}/c) \cdot (2 \ln 2 kT/m)^{1/2} = 3.58 \times 10^{-7} \cdot \nu_{ul} \cdot (T/m)^{1/2}$, where m is the molecular mass in g mol^{-1} and T is in K. The Voigt shape (convolution of collision and Doppler shapes) applies when both Doppler and collision broadening are important. Figure 3 shows representative linewidths versus altitude. The collision linewidth for O_2 is noticeably smaller than the others in Figure 3 because collision linewidths generally increase with dipole moment and O_2 has a very small (magnetic) dipole. Doppler broadening is important above $\sim 80 \text{ km}$ for the 22 GHz H_2O line, decreasing to above $\sim 40 \text{ km}$ for the 2.5 THz OH line.

The line shape function at the center of a collision-broadened line has value $1/(\pi \Delta\nu_c^{ul})$. Equation [7] then becomes [8], where $f \equiv n/N$ is the volume mixing ratio of the gas whose spectral line is being measured, N being atmospheric total number density, $\Delta\nu_c^{ul} \propto \rho T^{-x} \propto NT^{1-x}$ has been used, and all transition and frequency-dependent terms, and constants, are placed in $S_{ul}(T)$.

Figure 3 Linewidth (half-width at half-maximum) versus altitude for some representative microwave spectral lines.

$$\alpha_{\nu_{ul}}^{ul} = \frac{f \mu^2}{Q(T)} S_{ul}(T) \quad [8]$$

Equation [8] shows that the intensity at center of a (low optical depth) collision-broadened line is proportional to the volume mixing ratio of the species. Figure 4 shows a spectral line for the same mixing ratio at the top, middle, and bottom of the stratosphere.

Chemical Species and Spectra

Many chemical species have spectral lines in the wavelength region considered here. It is useful to have a 'figure of merit' that, in some sense, indicates the typical strength of a microwave spectral line from a particular species and can provide a first step for exploring measurement feasibility. Extracting factors from eqn [8] that depend only upon the species' overall properties yields $M = f \mu^2 / Q$ as a 'figure of merit'. Abundance of the species is described by f , μ^2 describes its overall interaction strength with radiation, and Q roughly indicates the number of quantum states over which it is spread. Table 1 lists stratospheric species in order of decreasing M for approximate maximum abundances in the stratosphere. Symmetric molecules (e.g., CH_4 and CO_2) with no dipole moment and no microwave spectra are missing, as are complex molecules (e.g., chlorofluorocarbons) having large partition functions that cause their 'figure of merit' to be lower than those included in the table. Examination of a species' spectrum, and – to avoid interference – the spectra of other species having M greater than ~ 10 times below that of the targeted species, is required to determine measurement feasibility and the spectral line(s) best suited. A catalog maintained by the Molecular Spectroscopy Group at the California Institute of Technology Jet Propulsion Laboratory (see World Wide Web site <http://spec.jpl.nasa.gov>) has microwave line parameters for the species in Table 1, and many more. Line frequencies are typically known to $\sim 0.1 \text{ MHz}$ or better; strengths to $\sim 1\%$ or better. Dipole (and other) moments are measured from Stark and Zeeman splitting of

Figure 4 Microwave emission lines for the same mixing ratio of a gas at the bottom (100 hPa, $\sim 15 \text{ km}$), middle (10 hPa, $\sim 30 \text{ km}$), and top (1 hPa, $\sim 50 \text{ km}$) of the stratosphere.

Table 1 Stratospheric species in decreasing order of the microwave 'figure of merit' $M = f\mu^2/Q$, where f is abundance in volume mixing ratio (column 5), μ is the dipole moment (column 3, where 1 Debye = 10^{-18} esu cm = 3.34×10^{-30} C m), and Q is the spin-rotation partition function (column 4, for a typical stratospheric temperature of 225 K). Excited vibrational states, indicated in parentheses (e.g., $2\nu_2$ indicates the second excited state of the second vibrational mode), are treated as separate species. The right column indicates if a microwave spectral line from that species has been detected by instruments from ground 'G', aircraft 'A', balloon 'B', or satellite 'S'. '(S)' indicates a satellite instrument to measure this molecule is planned for the near future. Species having $\log_{10}(M) \geq -14.3$ are included here

Species	$\log_{10}(M)$	Dipole moment (Debye)	Partition function at 225 K	Maximum stratospheric abundance (approximate)	Microwave detected from
O ₂	-6.4	0.0186	1.64×10^2	2.1×10^{-1}	G, A, B, S

^aAbundance and measurements are for enhanced SO_2 injected into the stratosphere by a volcanic eruption. Background SO_2 abundance in the stratosphere is $\sim 10^{-11}$, corresponding to.

^bThe 250 GHz spectral line due to thermospheric NO has been measured.

Updated from Waters JW (1993) Microwave limb sounding. Ch. 8 in Janssen MA (ed.), Atmospheric Remote Sensing by Microwave Radiometry. New York: John Wiley; Spectroscopic data from 9 Oct 2001 revision of the JPL Submillimeter, Millimeter, and Microwave Spectral Line Catalog, available on the world wide web at <http://spec.jpl.nasa.gov>.

spectral lines, allowing line strengths to be determined without requiring measurement of the gas abundance in a laboratory cell. Linewidth parameters can be measured with $\sim 3\%$ accuracy.

Figure 5 shows, on a very compressed scale, representative spectra including those of radicals involved in the major chemical cycles for stratospheric ozone destruction. Figure 6 shows an expanded region near 625 and 650 GHz where the strongest rotational line of ClO and the first rotational line of HCl occur.

Instrumentation

Figure 7 gives a typical block diagram of a microwave instrument for atmospheric chemistry observations. Atmospheric

signals are collected by an antenna, possibly amplified or filtered, and passed to a mixer. The mixer combines the atmospheric signal with a monochromatic local oscillator (LO) signal in a nonlinear process that reproduces the signal spectra at frequencies that are sums and differences of the atmospheric and LO signal frequencies, and possibly at their harmonics. State-of-the-art mixers are based on planar Schottky diodes (either cooled or room temperature), superconductor-insulator-superconductor (SIS) tunnel junctions, or superconducting hot electron bolometer (HEB) devices. The LO frequency is chosen so that the mixing product of interest (usually at the difference between the LO and signal frequencies) appears at intermediate frequencies (IFs) convenient for further processing. The IF signal, after amplification, is

Figure 5 Spectra of some stratospheric molecules and atomic oxygen. Vertical axis is the logarithm of the optical depth for an observation path through the atmospheric limb with the indicated volume mixing ratios (vmr). Reproduced with permission from Waters JW (1993) Microwave limb sounding. Ch. 8 in Janssen MA (ed.). Atmospheric Remote Sensing by Microwave Radiometry. New York: Wiley. © 1993 John Wiley.

passed to a spectrometer that separates it into individual spectral channels with desired resolution. Each channel's signal is then 'detected' (converted to a voltage proportional to its power and digitized), and passed to the data-handling system. Instruments often contain multiple mixers, LOs, IF amplifiers, and spectrometers to allow simultaneous observations of

Figure 6 Measured (crosses, bars) and calculated (thin line) stratospheric emission spectrum in bands measured simultaneously near 626 and 649 GHz. 'USB' refers to the frequency covered by the upper sideband of the radiometer, 'LSB' to the lower sideband, and 'IF' to the intermediate frequency (see discussion in 'Instrumentation' section of text). LSB spectral lines are in bold face (e.g., **HO₂**); USB lines are in italic face (e.g., *HO₂*). Adapted from Stachnik RA *et al.* (1992) Submillimeterwave heterodyne measurements of stratospheric ClO, HCl, O₃ and HO₂: first results. Geophysical Research Letters 19: 1931–1934.

several spectral lines. LO frequencies can be changed operationally to change measurements. Radiometers can be 'chopped', to reduce amplifier gain variation effects, by rapidly moving a 'reference' target in and out of the signal path or by frequency-switching the LO. An instrument sufficiently stable between calibrations does not require chopping and has twice the sensitivity of an otherwise identical symmetrically chopped instrument.

Calibration is performed by inserting targets (typically blackbody targets, with 'cold space' generally used for one when possible) in the signal path near the instrument input, ideally before the antenna. 'Double sideband' (DSB) radiometers receive signals in two mixer 'sidebands', at IFs above and below the LO, whereas 'single sideband' (SSB) radiometers receive signals in only one sideband. The DSB thermal calibration signal, coming through both sidebands, is twice that for SSB. A spectral line occurring in one sideband appears half as strong when (thermally) calibrated DSB as when calibrated SSB. Accurate calibration can require measuring and accounting for the responses in the two sidebands.

The sensitivity of a microwave radiometer is usually specified by its 'receiver noise temperature', a quantity – analogous to 'brightness temperature' – that is proportional to the instrument noise power referenced to the instrument input. The root mean square measurement noise, expressed in temperature, for integration time Δt and spectral resolution $\Delta \nu$ is given by eqn [9].

$$\Delta T_{\text{rms}} \approx a \frac{T_{\text{rec}} + T_{\text{sig}}}{\sqrt{\Delta t \Delta \nu}} \quad [9]$$

T_{rec} is the receiver noise temperature, and $a \approx 1$ for a non-chopped system or $a \approx 2$ for a chopped system. T_{sig} , usually much smaller than T_{rec} (except for solar absorption measurements), is present because the signal itself is noisy. The value of T_{rec} is primarily set by noise in the first amplifier and the amount of signal loss preceding it. Advances in technology are rapidly reducing noise and extending spectral bandwidth. Current values of T_{rec} (SSB values, or $2 \times$ DSB values) for the ~ 200 – 300 GHz range with ~ 0.5 GHz bandwidth are ~ 2000 K for room-temperature radiometers and ~ 400 K for SIS radiometers. Bandwidth can be increased at the cost of somewhat increased noise: room temperature radiometers at ~ 200 GHz have been developed with $T_{\text{rec}} \approx 4000$ K and ~ 15 GHz IF bandwidth. The measurement noise with $\Delta \nu = 16$ MHz resolution and $\Delta t = 1$ s integration, for example, is $\Delta T_{\text{rms}} \approx 1$ K for $T_{\text{rec}} \approx 4000$ K and $\Delta T_{\text{rms}} \approx 0.1$ K for $T_{\text{rec}} \approx 400$ K. Increasing the integration time to 1 hour gives $\Delta T_{\text{rms}} \approx 0.02$ K for $T_{\text{rec}} \approx 4000$ K and $\Delta T_{\text{rms}} \approx 0.002$ K for $T_{\text{rec}} \approx 400$ K. Microwave radiometer noise generally increases with frequency, but this can be offset by increases in line strength. A 22 GHz radiometer for ground-based stratospheric H₂O measurement ($T_{\text{sig}} \sim 0.2$ K) has $T_{\text{rec}} \approx 100$ K with ~ 0.5 GHz bandwidth and 20 K cooled first-stage transistor amplifier. A 2.5 THz room temperature radiometer with ~ 15 GHz IF bandwidth developed for satellite OH measurements ($T_{\text{sig}} \sim 100$ K) has $T_{\text{rec}} \approx 20\,000$ K. HEB radiometers at 2.5 THz have been constructed recently with $T_{\text{rec}} \approx 3000$ K and ~ 10 GHz bandwidth; improvements are expected as this technology matures.

Several types of spectrometers are currently used. Filter banks have a set of simultaneously observed spectral filters, usually

Figure 7 Typical block diagram of an instrument for microwave observations of stratospheric chemistry. The 'radiofrequency' amplifier is currently available only at lower frequencies and does not appear in many systems; a filter is sometimes placed at this position to eliminate unwanted signals in one of the mixer's sidebands. The portion of the instrument between the antenna and spectrometer is called the 'receiver' or 'radiometer'.

made of discrete or distributed capacitive and inductive elements, whose frequencies and widths are set as needed for a particular measurement. Digital autocorrelators measure a signal's autocorrelation simultaneously at many time lags; Fourier transforming the measured autocorrelation function gives the spectrum. Acousto-optic spectrometers use the IF signal to modulate a Bragg cell which, according to the signal's spectral content, diffracts a laser beam to a detector array. Chirp transform spectrometers multiply the IF signal by a frequency-modulated (chirp) waveform and convolve the resulting product with a filter that is appropriately matched to the chirp, and the spectrum appears as a function of time at the output.

Ground-Based Observations

Ground-based observations can provide continuous monitoring at selected sites. Instrumentation can be upgraded and repaired if needed, and can rapidly respond to changing priorities and atmospheric conditions. Vertical resolution is obtained from the spectral line shape and is typically around one atmospheric pressure scale height ($\sim 6\text{--}8$ km) but can be somewhat smaller with good signal to noise. Initial ground-based microwave measurements in the 1970s included stratospheric and mesospheric O_3 from lines near 100 GHz, and high-rotational lines of O_2 (on the edge of its 60 GHz spin-rotation band) that are very sensitive to stratospheric temperatures. Mesospheric CO was first measured by 115 GHz ground-based observations, with many later measurements at 230 GHz. Early measurements of the 22 GHz H_2O line showed a dry stratosphere, in contrast to many previous balloon *in situ* measurements (now thought to have been contaminated) that indicated a very wet stratosphere.

Ground-based microwave measurements have provided important results for understanding stratospheric chlorine chemistry. In 1981 they gave the first definitive remote measurements of ClO, the key chlorine radical involved in ozone depletion. Early results also included the first measurement of ClO diurnal variation, testing crucial aspects of upper stratospheric chlorine chemistry. In 1986 the technique gave the first evidence of greatly enhanced ClO in the Antarctic lower stratosphere, firmly connecting chlorine chemistry to the ozone hole. **Figure 8** shows an example of ClO evolution observed over Antarctica. Measurements of ClO diurnal variation tested chemical models for formation and photolysis of the ClO dimer in the Antarctic lower stratosphere. Enhanced ClO in the

Arctic winter stratosphere also has been measured. HNO_3 , important in processes involving polar stratospheric clouds (PSCs) and quenching of reactive chlorine, has been measured, as has N_2O , which gives information on dynamics.

Additional results include measurement of stratospheric HCN, and studies of mesospheric HO_x chemistry from

Figure 8 Ground-based 278 GHz measurement of stratospheric ClO over Antarctica. ClO is the key chlorine radical involved in ozone destruction. (a) Day–night differences of the spectral line measured during several days in 1992. (b) A height–time cross-section of the retrieved ClO mixing ratio profile, where contours are in parts per billion by volume. Reproduced with permission from deZafra RL, Reeves JM, and Shindell DT (1995) Chlorine monoxide in the Antarctic spring vortex 1. Evolution of midday vertical profiles over McMurdo Station, 1993. *Journal of Geophysical Research* 100: 13999–14007. © 1995 American Geophysical Union.

measurements of HO₂, O₃, and H₂O. The O₂¹Δ_g excited electronic state in the mesosphere has been measured, including diurnal variation, and implications were obtained for its radiative lifetime and chemistry. Zeeman splitting of mesospheric O₂ lines has been measured. The 250 GHz line from thermospheric NO has been measured. Ground-based microwave instruments are currently used by several research groups, and are deployed in the international Network for the Detection of Stratospheric Change to measure stratospheric ClO, O₃, and H₂O.

Aircraft-Based Observations

Aircraft-based observations can provide measurements with good horizontal resolution along a measurement track over an extended spatial range. Instruments can observe in high-frequency spectral windows where tropospheric H₂O absorption (Figure 1) prevents ground-based measurements and where more species have spectral lines. Vertical resolution is obtained from spectral line shape for measurements above the aircraft altitude, and can be obtained from limb sounding techniques at heights below the aircraft. Initial aircraft measurements in the 1970s included stratospheric H₂O and O₃ from lines near 183 GHz, and an upper limit on stratospheric ClO abundance. Recent measurements include stratospheric HCl, ClO, O₃, HNO₃, N₂O, H₂O, HO₂, BrO, and volcanic SO₂ from a 600 GHz SIS radiometer. Figure 9 shows HCl and ClO results from

Figure 9 Aircraft measurements of stratospheric HCl (triangles, from the 626 GHz line) and ClO (diamonds, from the 649 GHz line) from a January 2000 flight through the edge of the Arctic vortex. Measurement time for each point is ~1 min for HCl and ~3 min for ClO. These results show the transition of stratospheric chlorine from the relatively inert HCl at lower latitudes to the highly reactive ClO at higher latitudes inside the vortex. Gaps in the measurements around 54–56° N are where the instrument was tuned to measure HNO₃ and N₂O. The instrument and campaign in which these measurements were made are described by Bremer H, *et al.* (2002) Ozone depletion observed by the Airborne Submillimeter Radiometer (ASUR) during the Arctic Winter 1999/2000. *Journal of Geophysical Research* 107, No. D20, 8277, 10.1029/2001JD 000546.

a flight through the edge of the Arctic vortex. OH and H₂O have been measured from aircraft with a room-temperature 2.5 THz radiometer.

Balloon-Based Observations

Balloon-based microwave observations can provide measurements throughout the stratosphere with 2–3 km vertical resolution. The instrument FOV is vertically scanned through the atmospheric limb to observe a long path length and to obtain the vertical resolution. Balloon instruments provide measurements to higher altitudes with better resolution than can be obtained from aircraft or ground, and provide valuable development and tests of techniques to be deployed on satellites. Initial measurements in the 1980s were of ClO and O₃ from lines near 205 GHz. A 600 GHz room-temperature instrument for measuring HCl, ClO, HNO₃, N₂O, O₃, and HO₂ became operational in the early 1990s; some results are shown in Figure 10. Simultaneous measurement of HCl and ClO gives a stringent monitor of stratospheric chlorine chemistry, and first results from the 600 GHz balloon instrument showed that the ClO/HCl ratio in the mid-latitude upper stratosphere could not be explained by chemical models current at the time. Reaction of OH and ClO producing HCl, hypothesized as cause of the discrepancy, has since been measured in the laboratory with a rate that adequately explains the observations. Arctic winter flights have provided information on chlorine partitioning for perturbed chemistry in the vortex. Stratospheric OH has been measured at 2.5 THz from a balloon instrument that is a precursor for satellite observation.

Satellite-Based Observations

Satellite-based observations can provide global coverage on a daily basis. However, instruments cost more and require longer development time than for other platforms. Limb sounding is used for chemistry observations because of its vertical resolution and long path length for observations of small concentrations. Low-orbit (~700 km altitude) satellites have an observation path tangent point ~3000 km from the instrument. Vertical resolution of ~3 km, for example, then requires an antenna having vertical dimension of ~1000 wavelengths. Vertical pointing information is obtained from optically thin O₂ emission and spectral line shapes.

The need for global measurements of ClO motivated initial development of a satellite microwave instrument for stratospheric chemistry. The Microwave Limb Sounder (MLS), operating unchopped in bands around 63, 183, and 205 GHz, was developed to measure ClO, O₃, and H₂O from NASA's Upper Atmosphere Research Satellite (UARS) launched in 1991. A somewhat similar instrument, the Millimeter-wave Atmospheric Sounder (MAS) was flown on three Space Shuttle missions between 1992 and 1994. MLS results showed enhanced ClO filling the lower stratosphere polar winter vortices of both the Antarctic and Arctic. This finding was especially important for the Arctic, demonstrating the effectiveness of localized polar stratospheric clouds in activating chlorine throughout the vortex. Observed ozone loss during

Figure 10 Balloon microwave measurements of ClO, HCl, and HO_2 . Top panels show the spectral lines for a limb observation path through the middle stratosphere: measurements are the horizontal bars whose widths give the spectral resolution of individual filters and smooth lines are calculated. Fine structure features are seen in the HCl line. The bottom panels show retrieved mixing ratio profiles (thick) and uncertainty limits (thin). Adapted from Stachnik RA, *et al.* (1992) Submillimeter wave heterodyne measurements of stratospheric ClO, HCl, O_3 and HO_2 : first results. *Geophysical Research Letters* 19: 1931–1934.

Figure 11 Earth's lower stratosphere in the Northern Hemisphere on 20 February 1996 (top) and in the Southern Hemisphere on 30 August 1996 (bottom). White contours show the dynamical edge of the polar vortices. HNO_3 , ClO and O_3 are from the Microwave Limb Sounder on the Upper Atmosphere Research Satellite (no measurements are made in the white areas near the poles due to orbit limitations). Temperature data are from operational analyses of the US National Center for Environmental Prediction. Temperatures in the blue and violet color ranges allow formation of polar stratospheric clouds from HNO_3 and H_2O ; heterogeneous chemistry on these clouds leads to enhanced ClO that causes chemical depletion of O_3 . HNO_3 also provides a source of NO_x , which quenches ClO and reduces the amount of ozone destruction. Both HNO_3 and O_3 increase in the lower stratospheric vortices during early winter due to downward transport of air rich in these species. The amount of ozone destruction each winter in the polar vortices depends on the duration of enhanced ClO, which is longer for the Antarctic than the Arctic. This difference is traceable to the Antarctic lower stratosphere being colder, and remaining cold for longer, than the Arctic. periods of enhanced ClO is generally consistent with that expected from the ClO amount. MLS found that enhanced ClO appears in the edge of the Antarctic vortex by late May or early June each year and that by late July or early August the depletion of ozone by chlorine starts to dominate increases in ozone by transport. HNO_3 has been measured, providing insights into PSC microphysical processes and quantifying differences in denitrification (removal of nitrogen) between the Arctic and Antarctic. Figure 11 shows examples of daily maps of temperature, HNO_3 , ClO, and O_3 . Latitudinal variation in upper stratospheric zonal mean ClO from MLS appears

Figure 12 The weak 204 GHz H_2O_2 line from satellite measurements made over a period of 38 days, selected for tangent point pressure between 1 and 0.3 hPa (~ 2 days averaging time for the results shown here). Horizontal bars give the spectral resolution of individual filters and vertical bars give the $\pm 1\Delta T_{\text{rms}}$ measurement uncertainty calculated from eqn [9] for $T_{\text{rec}} = 1000$ K DSB of the unchopped satellite instrument. The line strength corresponds to $\sim 10^{-10}$ H_2O_2 volume mixing ratio in the upper stratosphere and lower mesosphere. The 0.353 K background is emission from the lower atmosphere received through the antenna sidelobes.

qualitatively consistent with that expected from variations in CH_4 . Global ClO variations over a 6-year period have been related to CH_4 variations, increases in total chlorine, and changes in lower stratospheric chemistry associated with the decrease of aerosol from the Mt. Pinatubo volcano. MLS and MAS ClO measurements agree to within ~ 0.1 ppbv where comparisons have been possible.

MLS measurements of H_2O led to the discovery of the atmospheric 'tropical tape recorder' whereby H_2O entering the tropical stratosphere is imprinted with a signature (the corresponding H_2O saturation mixing ratio) of the seasonally varying tropopause temperature. They showed that mid-latitude interhemispheric H_2O differences are not strongly related to the Antarctic winter vortex dehydration. Information has been obtained on various types of atmospheric oscillations and waves that affect the distribution of chemical species. Upper tropospheric H_2O , key for understanding aspects of climate variability, has been measured. The vertical profile of stratospheric SO_2 injected into the stratosphere by the Pinatubo volcano was measured for up to 6 months after the eruption, and its decay rate was shown to be consistent with that expected from reaction with OH. Stratospheric CH_3CN has been measured. Weak signals can require averaging of data taken over long periods, which is feasible from satellites as well as from the ground. Figure 12 shows a weak H_2O_2 line measured by averaging MLS data taken over 38 days.

ODIN, a small Swedish satellite launched in 2001 for time-sharing atmospheric and astronomical observations, has microwave radiometers in bands centered near 118, 495, 550, 557, and 570 GHz to measure stratospheric H_2O (and its minor isotopic variants H_2^{17}O , H_2^{18}O , and HDO), O_3 , ClO, N_2O , HNO_3 , CO, H_2CO , NO, HO_2 , H_2O_2 , and temperature. A next-generation MLS for NASA's Earth Observing System, has radiometers in five broad bands centered near 118, 190, 240, 640 GHz, and 2.5 THz to make measurements throughout the stratosphere and upper troposphere as shown in Figure 13. Japan is developing an SIS instrument for the International

Figure 13 Measurements planned for the Earth Observing System Microwave Limb Sounder scheduled to begin operations in 2003 on NASA's 'Aura' satellite. P is pressure and Z is geopotential height. P, Z, H_2O , O_3 , HCl, OH, and CO measurements extend higher than the 60 km shown here. Closed circles indicate where averages will likely be required, and open circles at lowest altitudes are goals for more difficult measurements. Synopsis

The main categories of chemical change important in atmospheric chemistry are homogeneous thermal gas-phase reactions, heterogeneous reactions on surfaces and within droplets, and photochemical reactions driven by solar radiation. Evolution from the reactants to the products is constrained by the energetics of the system, described by a potential-energy surface. The characteristics and mechanisms of unimolecular, bimolecular, and termolecular gas-phase reactions of both neutral and ionic species are presented. Four significant types of heterogeneous process are considered, and differences between gas-phase and condensed-phase behavior are examined. Absorption of visible and ultraviolet solar radiation may electronically excite atoms and molecules; the several possible fates of the excited species determine the pathways of atmospheric photochemistry.

Equilibrium and Change

Chemical change is essentially a reflection of a disequilibrium situation, in which a system employs excess free energy in order to drive spontaneous chemical processes. Ultimately, a condition of minimum free energy is reached, which corresponds to chemical equilibrium. The rates at which change occurs are the subject of *reaction kinetics* (see **Chemistry of the Atmosphere: Chemical Kinetics**). In this article, emphasis is placed on the types of chemical process that occur, with special reference to the atmosphere.

Homogeneous Gas-Phase Reactions

Chemical reactions are conveniently categorized by their *molecularity*. For an *elementary reaction*, the molecularity is the number of 'particles' (the word is used here to represent atoms or molecules) participating in the process of interest (see **Chemistry of the Atmosphere: Chemical Kinetics** for further details).

Bimolecular Processes

Bimolecular processes represent a good starting point for the discussion of chemical change, since they involve a fully developed interaction between two reactant species. When two particles approach each other closely enough, the energy of the system increases as the particles experience repulsive forces. Consider the interaction of an atom A with a molecule BC. The positions of the A, B, and C atoms can be defined in terms of their interatomic distances r_{AB} , r_{BC} and the A...B...C bond angle. That is, four dimensions are required to define energy in terms of the geometric coordinates. For a defined bond angle (for colinear approach, say), the reduced three-dimensional potential-energy surface (PES) can be represented by a two-dimensional contour map, as in **Figure 1(a)**. It is now useful to distinguish three different outcomes of the approach of A and BC, shown schematically in **Figure 1(b)**, **1(c)**, and **1(d)**. In **Figure 1(b)**, the pathway superposed on the PES shows the r_{AB} distance decreasing as A approaches BC, and the energy of the system increases up to the point at which the speed of approach becomes zero. At this point, the particles separate again on the same path along which they approached each other; they have undergone an *elastic collision*, in which all the energy is

conserved as translational motion. The process represented by **Figure 1(c)** is rather different, because the initial energy of interaction allows the particles to reach a part of the PES where there is an alteration of the geometry of the forces acting on BC. As a consequence, the return path is different from the approach path, with the B...C distance undergoing periodic oscillations. Translational energy has been converted to vibrational energy of BC in an *inelastic collision* that has brought about *energy transfer*. **Figure 1(d)** shows the final possibility, that of *reactive collision*. The motions of the particles now take them to the configuration where the distance r_{BC} is much larger than r_{AB} , so that the molecular species is now AB. That is, the reaction

has occurred. The contours of the surface suggest an analogy with mountainous terrain, in which there is a 'valley' that provides the lowest energy approach of the reactants, and the dotted line in the figure is that path. Beyond the point marked ' $\neq$ ', the energy starts to decrease again, and product formation is now energetically favorable. In the mountain analogy, the point $\neq$ is a 'col' or 'pass'; in terms of chemical kinetics, it is a *transition state*, of particular significance in a major theory of chemical kinetics (see **Chemistry of the Atmosphere: Chemical Kinetics**).

The reaction pathway (and the transition state) shown is only one of an infinite number of possibilities. In principle, if the PES is known, it is possible to calculate, using the laws of mechanics, the path followed for any initial 'starting' distance and direction of approach of the reactants A and BC. For a given speed, and internal excitation (vibration, rotation) of the reactants, the fraction of 'trials' leading to product formation can then be assessed, and this fraction is related to the probability of reaction. The ordinary macroscopic rate coefficient, k , (see **Chemistry of the Atmosphere: Chemical Kinetics**) can then be determined from a sum over the distributions of translational velocity, and vibrational and rotational excitation, appropriate to any temperature T : for thermal equilibrium, the *Maxwell-Boltzmann distribution* will be used. Such methods of *molecular dynamics* would be ideal for predicting rate coefficients if only it were possible to calculate from first principles the PESs for all reactions. Unfortunately, it is not yet feasible to perform these a priori calculations of surfaces, except for the very simplest reactions. Modern experimental kinetics can show the probability of passing from one set of reactant states

Figure 1 (a) Potential-energy surface for the system $A \cdots B \cdots C$ at a fixed bond angle; (b) elastic collision; (c) inelastic collision; and (d) reactive collision.

(translational, vibrational, rotational, etc.) to one set of product states: so-called *state-to-state kinetics*. The results of such experiments can then be used to test hypothetical PESs. In this case, however, the molecular dynamic calculations have lost their predictive value, and the simplifications described in the article **Chemistry of the Atmosphere: Chemical Kinetics** are usually employed instead.

It is now appropriate to examine the types of reactive bimolecular encounter that can occur in atmospheric chemistry. The most important are

1. atom or group transfer;
2. addition;
3. exchange (metathesis).

Reaction [I] is, of course, formally an example of atom transfer. Real examples of importance in atmospheric chemistry include the processes

Reactions [III] and [IV] are hydrogen-atom transfers, while **reaction [II]** is an oxygen-atom transfer.

Additions can be illustrated for atmospheric chemistry by the processes

We shall discuss reactions of this type further in connection with termolecular processes.

The third category of bimolecular reaction, the exchange process, is relatively rare in atmospheric chemistry (and, indeed, in gas-phase chemistry in general). Many apparent examples are, in reality, made up of several stages involving, as the bimolecular steps, transfers, and additions. A true exchange reaction requires the production of a multicenter transition state. One example from the atmosphere that illustrates the problem is that of the ozonolysis of a simple alkene

In this case, O_3 initially adds across the double bond of the propene to form A.

This species undoubtedly goes on to form the products given for the two branches of **reaction [IX]**, which appear to be those of an exchange reaction. The species may not, however,

satisfy the formal conditions for being a true transition state, but rather be an energy-rich adduct (ozonide). In this latter case, the reaction is bimolecular addition, followed by unimolecular decomposition (see later) of the adduct.

Reactions of Ions in the Gas Phase

A more convincing example than [reaction \[IX\]](#) of a genuine exchange reaction is afforded by a process of considerable significance in the ionosphere

This is an example of an *ion–molecule reaction*. Although many ion–molecule reactions have their counterparts in neutral chemistry, some others do not. Three bimolecular processes that are peculiar to ion–molecule reactions are the steps

In all three of these examples, it is the charge – positive or negative – that is involved in the unusual behavior.

Charge on the reactant species brings with it another influence on ion–molecule reactions, which is that the rate coefficients for reaction can be orders of magnitude larger than those for the comparable reactions for neutral reactants. This question is explored in more detail in the article **Chemistry of the Atmosphere: Chemical Kinetics**. The effect arises because of long-range attractive forces between the reactants. The PES of [Figure 1](#) shows a monotonic increase from large separations of the reactants until the transition state. For charged species, however, the Coulombic interactions may cause the energies to decrease at some separations, with the consequence that long-range attraction draws the species together. The effects are obviously greatest for ion–ion reactions in which the ions have charges of opposite signs, as they do, for example, in [reaction \[XII\]](#). Coulombic forces operate over shorter ranges between ions and neutral molecules possessing a dipole; even nonpolar neutral molecules experience some attraction as a result of dipoles induced as the ionic species approaches.

Unimolecular Reactions

If the species A introduced in connection with [reaction \[IX\]](#) is really an energy-rich adduct (rather than a transition state), then its subsequent decomposition to form the products of steps [\[IXa\]](#) or [\[IXb\]](#) is of the form

which is a *unimolecular decomposition*, since it involves only one chemical species in an elementary reaction step. A typical atmospheric example is the decomposition of the species $\text{ClOO}^\ddagger$

which is important in the chlorine-catalyzed destruction of stratospheric ozone. Although decompositions are the most important atmospheric unimolecular reactions, *isomerization*

is another unimolecular process that is of atmospheric significance. Alkoxy radicals, in particular, can undergo both

fragmentation and isomerization, depending on their structures. The alkoxy radicals derived from the products of [reaction \[Va\]](#) and [\[Vb\]](#) in the oxidation of propene, for example, fragment to yield carbonyl compounds and further hydroxyl radicals

while the 2-pentoxyl radical, which is an intermediate in the oxidation of *n*-pentane, undergoes isomerization

via a cyclic transition state.

The formation of the energy-rich species represented by $\text{AB}^\ddagger$ is easy enough to understand if the energy derives from chemical reaction, as it might do in the formation of the intermediate ozonide in [reaction \[IX\]](#). Photochemical excitation, to be discussed later in this article, is another way in which an energy-rich species might be formed. However, many of the unimolecular processes of interest are *thermal reactions*. The energy that drives them is gained initially by elastic collisions (see above) with other molecules, represented for this purpose by the symbol M, which is called in this context a *third body*.

For example, the thermal unimolecular dissociation of N_2O_5 consists of two steps; the first is the *thermal activation* by collision and the second is the real unimolecular decomposition

In the Earth's atmosphere, M is generally, of course, the mixture of the major gases N_2 and O_2 . It is the activation (and a corresponding deactivation) step that gives rise to the special kinetic behavior of unimolecular reactions that is presented in the article **Chemistry of the Atmosphere: Chemical Kinetics**. Experimental evidence has shown clearly that the energy already stored within a molecule (for example, as the thermal equilibrium population of vibration) can contribute to the energy required for dissociation, so that not all the energy has to come from the collisional activation step [\[XIX\]](#). It further appears that the energy can flow fairly freely between vibrational modes in a molecule, and that the rate of dissociation (or isomerization) of a molecule depends on the total excess energy possessed by the molecule over the critical energy required to bring about the chemical change under consideration. It is all these features taken together that must be accommodated in sophisticated theories of the kinetics of unimolecular reactions.

Termolecular Addition Reactions

One class of termolecular reaction is of particular note in atmospheric chemistry, and that is the one involving the combination (often, and usually erroneously, called 'recombination') of atoms and small radicals. The processes

are all of this kind. As explained in the article **Chemistry of the Atmosphere: Chemical Kinetics**, such reactions may be

kinetically third order, as the chemical equations suggest, but may also become second order at high enough pressures. Reaction [XXI] can be used to explain why the third body, M, is essential in many of the reactions, and thus needs to be written into the equation. Figure 2 shows some selected potential-energy curves for the O₂ molecule, of which the lowest ('ground state') is labeled 'X' and is the subject of the current discussion. This curve is equivalent (for BC = O₂) to a section of the PES of Figure 1(a) taken parallel to the abscissa, and at large r_{AB} . Even if the two O atoms only just drift toward each other at near-zero velocity along the asymptote at large O–O separation, the newly formed O₂ molecule nevertheless possesses enough energy to redissociate on the first vibration. Only if enough energy is removed from the O₂[†] during this vibration, is there the possibility that the newly formed entity will be stabilized sufficiently to survive as an O₂ molecule. It is there, of course, that the collision with M comes in. The rate-determining step is this stabilization up to pressures of several hundred bar for the atom + atom system, and the kinetics remain third order until such pressures are reached. The situation is changed if the newly formed molecule is larger than diatomic. The product molecules of reactions [XXI], [XXII], [XXIII], and [XXIV] possess two, three, five, and six atoms, implying zero, two, eight, and eleven internal vibrational modes in addition to vibration in the new bond. The point is that the bond energy of the newly formed molecule can flow into these vibrations to some extent during the first vibration of the new bond. The efficiency of energy flow increases with an increasing number of modes, so that the requirements for removal of the energy by external collisions become increasingly less stringent. Now, the demand is that a collision with M is required to remove energy before the bond energy reassembles in the critical bond. It may be that the collisional removal of energy is no longer rate determining, in which case the reaction becomes kinetically second order. These ideas are all explored in a more quantitative form in the article **Chemistry of the Atmosphere: Chemical Kinetics**. For reactions such as

Figure 2 Potential-energy curves for some selected states of molecular oxygen. The solid curves represent bound states, and the labels are here just used as identifiers. The actual electronic states are $X^3\Sigma_g^-$, $a^1\Delta_g$, $b^1\Sigma_g^+$, and $B^3\Sigma_u^-$. The states of atomic oxygen with which the different curves correlate are indicated on the asymptotes at large internuclear distances.

the combination of two polyatomic radicals, for example CH₃ and C₂H₅

the reaction would probably be second order, and apparently bimolecular, throughout the troposphere, the atmospheric region in which it is likely to occur. It is for this reason that the addition reactions [V]–[VIII] were written as simple bimolecular processes, even if, in principle, at a sufficiently low pressure a third body would be required to stabilize the products suggested. What is worth emphasizing is that the combination processes are really just another facet of the unimolecular chemistry discussed earlier, because the stabilization required is that of an energy-rich molecule, here formed by what is really just chemical activation.

The Energetics of Chemical Change

The enthalpy (ΔH_r) of a chemical reaction is the difference between the enthalpies of the products and the reactants, corresponding to the difference in limiting 'heights' between the extreme bottom right and extreme top left of any of the panels of Figure 1, so long as the energy is expressed in appropriate units. All the enthalpies are normally given for a 'standard' pressure or concentration, and at a specified temperature, but for simplicity this aspect is ignored here. The way in which the energy of the system changes as reaction progresses is more easily seen if the potential energy is plotted as a function of a distance coordinate corresponding to the distance traveled along the reactive pathway shown in Figure 1(d). Figure 3 is such a representation of energy as a function of *reaction coordinate*, in this case for an *exothermic* reaction (negative ΔH_r): for passage in the reverse direction (i.e., from AB + C to A + BC), the reaction is *endothermic* (positive ΔH_r). Regardless

Figure 3 Energy of a reacting system as the reaction proceeds. The energy is represented as a function of reaction coordinate, which is essentially the distance traversed along the reaction path marked in Figure 1(d). The enthalpy of reaction, and the activation energies for forward and reverse reactions are marked on the diagram to clarify the relation between these quantities.

of whether the reaction under consideration is exothermic or endothermic, it can be seen that there is nevertheless a barrier to reaction in either direction, which corresponds to the energy of the transition state relative to that of the starting species. As explained earlier, and discussed in more detail in **Chemistry of the Atmosphere: Chemical Kinetics**, this barrier is thought to be the explanation of the experimentally observed activation energy that results in most thermal bimolecular reactions showing an increase in rate with increasing temperature.

Figure 3 makes clear a simple relationship between the barrier heights (and, therefore, expected activation energies) for forward and reverse reactions and the enthalpy of reaction. If the barrier heights are E_c^f and E_c^r , then

$$E_c^r = E_c^f - \Delta H_r \quad [1]$$

In principle, the vibrational zero-point energies of the reactants and transition state ought to be included in calculating the energy required to pass over the barrier. Indeed, at elevated temperatures, the calculation should provide a weighted mean for all the populated vibrational levels. Experimental evidence clearly supports this theoretical notion, since many reactions exhibit *kinetic isotope effects*, the most important of which is associated with zero-point energy differences. For example, in many H- or D-atom transfer reactions, vibrations that remain in the transition state do not involve the H or D atom. Vibrations in the reactants may, however, include those with -H or -D contributions. The lower vibrational frequency of the D-substituted species compared with the unsubstituted molecule puts the zero-point energy lower, and the barrier height to be surmounted is correspondingly larger. Rate coefficients for the deuterated species (k_D) are thus lower than those for the undeuterated molecule (k_H). Calculations of the vibrational frequencies suggest a maximum value for k_H/k_D of not much more than five at ambient temperature, and experimental observations give similar results for straightforward activated reactions, thus lending confidence in the association of activation energies with the height of the 'col' on the PES.

Heterogeneous Chemistry

The liquid and solid particles suspended in the atmosphere significantly influence the chemistry that can occur. Included in the category of atmospheric *heterogeneous chemical reactions* are not only those occurring at the interface between two phases, but also those in which initial transfer of reactants from the gaseous to a condensed phase is followed by homogeneous chemical change within that condensed phase. Atmospheric chemistry involving clouds, fogs, rain droplets, ice particles, and other solid and liquid aerosol particles requires transfer of gas-phase molecules to the condensed-phase system across the particle interface. Reactions occurring inside particles are confined to the liquid phase, since diffusion coefficients within solids are too small to allow significant reaction rates. On the other hand, reactions on solid surfaces are thought to be of very considerable atmospheric significance. An added degree of complexity arises when the particle is liquid, as is the case for droplets in the troposphere, and possibly for stratospheric sulfate aerosol, which may be in the form of supercooled liquid sulfuric acid.

Four simple categories can be recognized for the chemistry that creates aerosols and droplets, and occurs on and in them:

1. condensation of a single component;
2. reaction of more than one gas to form a new particle;
3. reaction of gases on a preexisting particle; and
4. reactions within the particles themselves.

Category (1), the condensation of a single gaseous component to form a new suspended particle is *homogeneous, homomolecular nucleation*. The most obvious example is the aggregation of sufficient H_2O molecules from the gas phase to produce a droplet of liquid, or particle of solid, water. Category (2) is the analogous process for reacting species involving two or more gases to form a condensable product species in a *homogeneous, heteromolecular process*. A typical example is the reaction between gaseous NH_3 and HNO_3 to form particles of NH_4NO_3 . But the same reaction can occur on a particle that already exists, a process that is a *heterogeneous, heteromolecular reaction* of type (3). Heteromolecular reactive condensation of gas-phase molecules on preexisting particles is sometimes called *aerosol scavenging*. It can have an impact on bulk tropospheric chemistry by providing a sink for nitrogen and hydrogen species such as HNO_3 , NO_3 , N_2O_5 , H_2O_2 , and HO_2 , as well as organic nitrates and peroxides. Clouds and raindrops have a major effect on gas-phase species through the scavenging mechanism. Finally, category (4) includes chemical reactions that occur within the aerosol itself to form particles of changed composition, as in the oxidation of SO_2 to sulfate ions in clouds. These are multiphase processes, since they involve transfer from (and perhaps back to) the gas phase.

How do gas-phase and condensed-phase reactions differ? The solvent may substantially alter the chemistry of a condensed-phase reaction. To start with, the solvent hinders free motion of the reactants, with the result that the assumptions made in developing theories of gas-phase kinetics are no longer valid. Further, and of potentially great importance, the reactants, activated complexes or intermediates, and products can also all interact with the solvent, perhaps making possible reactions that do not occur in the gas phase. For example, reactions in aqueous solution often involve ionic processes, because the high relative permittivity and polar nature of the solvent make reactant ionization energetically accessible. Another key difference is that an *encounter pair* of reactants may find themselves undergoing multiple collisions within a *solvent cage*, leading to interesting differences in the rates of reaction in gas and condensed environments. We are straying now into the field of chemical kinetics, and further discussion is more appropriately continued in **Chemistry of the Atmosphere: Chemical Kinetics**.

Photochemical Change

The reactions discussed so far have been 'thermal': that is, the driving force has been the exothermicity of the chemical change, and barriers to reaction have been overcome by the thermal translational energy of the reactants, and perhaps by their internal vibrational energy. Another class of reaction of enormous importance is that of *photochemical reactions*, in which the driving force is the absorption of radiation. An atmosphere is a giant photochemical reactor, in which the light

source is the Sun. Radiation, generally in the visible and ultraviolet regions, either fragments the atmospheric constituents to produce atoms, radicals, or ions, or excites the constituents, without chemical change, to alter their reactivity.

Planck's law states that the energy of one photon of frequency is $h\nu$, where h is Planck's constant. Photochemists therefore usually write ' $h\nu$ ' in chemical equations as a shorthand for the photon that is a reactant, as, for example, in the *photolysis* of ozone

Planck's constant is known, so that the energy per photon can be calculated immediately. A useful conversion expresses E in the molar units kJ mol^{-1} and employs the wavelength of radiation (λ in nm) rather than the frequency itself

$$E = 119625/\lambda. \quad [2]$$

Thus the red extreme of the visible spectrum (~ 800 nm) corresponds to about 150 kJ mol^{-1} , and the violet extreme (~ 400 nm) to twice that energy. At shorter wavelengths lies the ultraviolet, conventionally subdivided into 'near' (λ approximately 400–200 nm), 'vacuum' (VUV, λ approximately 200–100 nm), and 'extreme' (EUV, λ approximately 100–10 nm) regions, with successively higher energies. The photon energy of red light is comparable with the bond energies of rather loosely bound chemical species. Of common gaseous inorganic species, ozone is, in fact, the only compound with such a small bond energy (the O–O₂ energy is $\sim 105 \text{ kJ mol}^{-1}$); nitrogen dioxide, with an O–NO bond energy of $\sim 300 \text{ kJ mol}^{-1}$ ($\cong 399$ nm) is more typical. Ionization becomes possible at the shorter wavelengths (e.g., ionization of NO at $\lambda \sim 135$ nm). X-rays, gamma rays, and galactic cosmic radiation constitute the shortest ($\lambda < 10$ nm) wavelengths of the electromagnetic spectrum. The very high photon energies are associated with an ability to penetrate as well as to ionize atmospheric gases. The point to be emphasized is that the visible region contains the lowest energy photons of the entire electromagnetic spectrum that are capable of promoting chemical change in single quantum events. Many more photons arrive each second at a planet at longer wavelengths, but they can only heat the atmosphere up.

The wavelengths at which chemical change becomes possible also correspond roughly to the energies at which *electronic transitions* are excited in atoms and molecules. Longer wavelengths tend to excite molecular vibrations or rotations. Although high vibrational levels are involved in some photochemical processes, electronic excitation is the spectroscopic step most frequently associated with photochemical change. Even very weak, highly forbidden, transitions can contribute to atmospheric absorption because of the large optical paths involved. Small, light chemical species generally show intense electronic absorption at shorter wavelengths than more complex compounds. Molecular oxygen absorbs strongly for $\lambda < 200$ nm, H₂O for $\lambda < 180$ nm, CO₂ for $\lambda < 165$ nm, while N₂ and H₂ absorb significantly only for $\lambda < 100$ nm. It is the limitation on laboratory experiments in air, resulting from the O₂ absorption that has led to the term 'vacuum' ultraviolet for $\lambda < 200$ nm. Atmospheres tend to act as filters cutting out short-wavelength radiation, since the absorptions of their major constituents are generally strong at wavelengths shorter than

the threshold value. As a result, photochemically active radiation that penetrates deeper into an atmosphere is of longer wavelength, and the chemistry characterized by lower energies, than that absorbed higher up. The principle is well exemplified by the chemistry of Earth's atmosphere. Tropospheric photochemistry is dominated by species such as O₃, NO₂, SO₂, and HCHO, which absorb in the near-ultraviolet region. At progressively higher altitudes, photodissociation of O₂ and photoionization phenomena become the most important processes. At ground level, only radiation with $\lambda > 300$ nm ($\cong 400 \text{ kJ mol}^{-1}$) remains, and the peak intensity is at $\lambda \sim 500$ nm ($\cong 240 \text{ kJ mol}^{-1}$).

Photochemical Primary Processes

Absorption of a photon of photochemically active radiation leads to electronic excitation, a process that may be represented symbolically as

Many fates of the excited AB* molecule are recognized, and several of them occur in atmospheres. **Figure 4** summarizes the processes most frequently encountered, and they will be discussed briefly in turn.

Photodissociation, Photoionization, and Intramolecular Energy Transfer

Routes (i) and (ii) lead to *fragmentation* of one kind or another. Fragmentation of a chemical species following absorption of light is one of the most important photochemical processes in atmospheric chemistry. *Photodissociation* may come about when the energy of the absorbed photon exceeds the binding energy of the chemical bond under consideration. That is, the species AB* excited initially in the absorption event [XXVII] can lie energetically above the dissociation threshold in the molecule, and the bond can then rupture in some way. Two main mechanisms are recognized for this photochemical rupture. The potential-energy curves of **Figure 2** illustrate these processes for the photodissociation of the O₂ molecule. The molecule in its ground state, labeled in the diagram as X, can absorb ultraviolet radiation to populate the curve labeled B. If the wavelength of absorbed radiation is short enough that the B state is populated above the dissociation limit of the products O(³P) + O(¹D), then *direct dissociation* (also called *optical dissociation*) can lead to the formation of these fragments.

Process (iii) of **Figure 4** is *intramolecular energy transfer*, and can generate a new electronic state of the same molecule by a *radiationless transition*. The dashed curve in **Figure 2** for O₂ crosses the B state, and is populated by such transitions. This new electronic state of O₂ is *repulsive*, and falls apart to form the fragments O(³P) + O(³P). Both mechanisms are thought to operate in the atmospheric production of O atoms from O₂. The overall dissociative process is referred to as *predissociation*, and leads to the dissociation at lower energies (longer wavelengths) than are needed for direct dissociation. Note that the direct dissociation route produces an (electronically) excited atomic fragment, O(¹D), as well as a ground-state atom. Such excitation in the fragments of photodissociation is of common occurrence. Indeed, the photodissociation of O₃ by ultraviolet

Figure 4 Atmospherically significant fates of an electronically excited species, AB^* . The excitation is usually a result of absorption of visible or ultraviolet radiation. The symbols $*$ and $\#$ indicate different electronically excited states. Although the processes are written for a molecule AB , excited atoms can also decay via any of the pathways except (i) and (iii).

radiation, already represented by equation [XXVI], can produce two excited fragments

and both fragments are of importance in atmospheric chemistry. The curve labeled a in Figure 2 is, in fact, the potential-energy curve for the electronic state of O_2 formed in this atmospherically most important step.

Photoionization (process (ii) in Figure 4) may be regarded as a special case of photodissociation, but one in which the products are a positively charged ion and an electron. The reactions

are typical of photoionization. In general, the energies (*ionization potentials*) required to remove an electron from an atom or molecule are larger than those needed to split a molecule into chemical fragments. For example, the ionization process [XXX] requires $\lambda \leq 103$ nm. Mechanisms of photoionization are analogous to those for dissociation, both *direct ionization* and *preionization* (*autoionization*) being recognized. Excited electronic (and, in molecules, vibrational and rotational) states of the ions may be generated.

Luminescence or Emission

Pathway (iv) of Figure 4 is the emission of radiation, usually termed *luminescence*. A distinction is often made in photochemistry between radiative transitions that are allowed, in which case the phenomenon is termed *fluorescence* and those in

which it is forbidden, in which case the phenomenon is *phosphorescence*. Such emission is responsible for many important features of the *atmospheric airglow*. For example, both the excited species formed in reaction [XXVIII] contribute to the *dayglow*.

Chemical Reaction

Pathway (v) shown in Figure 4 is that of *chemical reaction*, in which species are formed that are chemically distinct from the starting reactants. It includes all processes where reaction is possible only for, or rates are enhanced with, electronically excited reactants. The chemical reactivity of an electronically excited species may be altered from that of the ground state both as a result of the excess energy that it possesses and because of the altered electronic structure. Two very important examples of the chemical reaction of an excited species in the atmosphere again involve the atom $O(^1D)$. The reactions of ground-state, $O(^3P)$, atoms with H_2O and N_2O are endothermic, and very slow under atmospheric conditions, while the reactions with excited atoms

are exothermic and fast, and make essential contributions to the formation of OH and of NO in various regions of the atmosphere.

Intermolecular Energy Transfer and Quenching

Intermolecular energy transfer, route (vi) of Figure 4, excites a molecule that is often chemically distinct from the absorbing species. An atmospheric example can be drawn from the airglow of oxygen yet again. Figure 2 shows a curve labeled b; this curve represents the electronic state $O_2(b^1\Sigma_g^+)$ which contributes to the airglow at $\lambda \sim 760$ nm. Some of the $O_2(b^1\Sigma_g^+)$ is populated by direct absorption of solar radiation during the day, but an additional contribution is made by the energy-transfer process

That is, the excited oxygen atom has transferred (some of) its excess energy to the O_2 .

Quenching or *deactivation* (pathway vii) is a special case of intermolecular energy transfer, where electronic excitation is degraded to vibrational, rotational, and translational modes. It competes with the other routes for decay of an electronically excited species. For example, the rapid quenching reaction

imposes a limit on the extent of OH or NO formation in reactions [XXXIII] or [XXXIV], especially in view of the relatively small mixing ratios of H_2O or N_2O compared to N_2 . Since quenching is a bimolecular process, it is pressure- (and therefore altitude-) dependent. Thus the competition with unimolecular processes such as emission means that airglow features often show a marked intensity decrease with decreasing altitude.

Introduction

The Earth receives a great variety of radiations at the top of the atmosphere, over a very wide range of energies. Among these, the only radiation that is capable of producing significant changes in the isotopic composition of matter is the cosmic radiation. Nuclear interactions of cosmic ray particles with the constituent nuclei of the atmosphere produce several stable and radioactive nuclei. These nuclides (isotopes of elements) are termed cosmogenic nuclides or cosmogenic isotopes. Thus the atmosphere is continually labeled 'naturally' by nuclides, which serve as tracers for studying the nature of large-scale motions of the atmosphere: their distribution allows one to directly determine the nature of the large-scale air circulation, as well as the time scales of their removal from the lower atmosphere by wet precipitation and dry deposition. These tracers have several unique features: (1) the source functions of the tracers in all parts of the atmosphere can be determined precisely as a function of time; (2) several radionuclides with different chemical properties and half-lives varying in the range of an hour to more than a million years are produced by cosmic rays, whereby air transport/mixing and aerosol scavenging processes by wet precipitation can be studied quantitatively, on time scales ranging from hours to years.

The usefulness of tracers in fluids undergoing complex, space- and time-dependent motions cannot be underestimated. They provide space–time integrals of motion on time scales of the mean lives of the nuclides. It is interesting to note that a quantum jump in our understanding of the atmospheric processes occurred in the 1950s when artificial radionuclides were introduced in the atmosphere as a result of nuclear weapons tests. The spring 1954 Castle thermonuclear test introduced a large amount of artificial ^3H (tritium: half-life 12.3 years) into the atmosphere. Studies of its concentration in rains clearly showed that it was removed from the atmosphere in periods as short as weeks. Similarly, the injections of the fission radionuclide ^{90}Sr into the atmosphere in stratospheric tests of nuclear weapons led to the first insight into time scales of removal of aerosols from the stratosphere to the troposphere and finally onto the surface of the Earth, within periods of the order of few years. These were remarkable observations indeed, since conventional physical meteorological studies did not provide even rough estimates of the time scales involved in circulation and self-purging of the atmosphere, although enough was known about the physical state of the atmosphere. However, a model had then been proposed for the grand Equator-to-Poles troposphere–stratosphere–troposphere circulation, namely the Brewer–Dobson model, which remained controversial until recently.

The naturally produced cosmogenic radionuclides ^{14}C (half-life 5730 years) and ^3H had been discovered before the first Castle test in the atmosphere, in 1947 and 1951, respectively. Soon thereafter, in the mid-1950s, the long-lived radionuclide ^{10}Be (half-life 1.5 million years), and several

short-lived cosmogenic radionuclides (^{22}Na , ^{35}S , ^7Be , ^{33}P , and ^{32}P) with half-lives in the range of weeks to years were discovered. Additionally, seven short-lived radionuclides of half-lives ranging from 30 min to 20 h were detected. See Table 1 for half-lives and production mechanisms of the cosmogenic nuclides. Studies of their distribution in the atmosphere and in wet precipitations showed clearly the power of these nuclides as tracers for studying wide-ranging problems in atmospheric dynamics. The great attraction of tracers of different half-lives in such studies lies in the fact that they allow integration of complex fluid motion over very different space and time scales, and the greatest virtue of cosmic ray tracers lies in the fact that they are naturally injected into the atmosphere continuously at a rate that can be determined fairly accurately. Fortunately, tracers of different half-lives and chemical properties are available to answer most of the important questions in atmospheric transport and removal processes.

The importance of the study of atmospheric transport and aerosol scavenging processes cannot be overemphasized. First, it must be considered as the central problem in physical and chemical meteorology, which should in fact appear as a tangible

Table 1 Cosmogenic nuclides^a produced in the Earth's atmosphere with half-lives exceeding 30 min

Nuclide	Half-life	
	(s = stable)	Main target nuclei
^3H	12.3 years	N, O
^3He	s	N, O
^7Be	53 days	N, O
^{10}Be	1.5×10^6 years	N, O
^{14}C	5730 years	N, O
^{20}Ne , ^{21}Ne , ^{22}Ne	s	Ar
^{22}Na	2.6 years	Ar
^{24}Na	15 h	Ar
^{26}Al	7.1×10^5 years	Ar
^{28}Mg	21.2 h	Ar
^{31}Si	2.6 h	Ar
^{32}Si	~ 150 years	Ar
^{32}P	14.3 days	Ar
^{33}P	25.3 days	Ar
$^{34\text{m}}\text{Cl}$	32 min	Ar
^{35}S	87 days	Ar
^{36}Cl	3.0×10^5 years	Ar
^{37}Ar	35 days	Ar
^{38}Cl	37.3 min	Ar
^{38}S	2.9 h	Ar
^{39}Cl	55.5 min	Ar
^{39}Ar	268 years	Ar
^{81}Kr	2.3×10^5 years	Kr
^{129}I	1.6×10^7 years	Xe

^aArranged in order of increasing mass number.

product of studies of the physical structure of the atmosphere. Second, it is a prerequisite in understanding the chemistry of the atmosphere. Finally, with the increased injections of a variety of chemical compounds as a result of industrial activity, including CO_2 , fluorocarbons, CCl_4 , etc., it becomes necessary to develop a quantitative capability to estimate the evolution of their distributions in the atmosphere, in space and time. This is being accomplished using a variety of tracers: those produced naturally and those produced artificially. Radon-222 (^{222}Rn) is a naturally produced tracer. In view of its short half-life (3.8 days) and because it is injected into the atmosphere from the Earth's surface, it is especially useful for characterizing air motions in the lower troposphere. The production rates of cosmogenic nuclides are highest in the stratosphere, but still appreciable in the troposphere. They can therefore be used as tracers throughout the atmosphere. As will become clear later, cosmogenic nuclides show great potential for quantifying atmospheric transport and aerosol scavenging processes, as demonstrated in several experiments carried out since the mid-1960s. However, their full potential has yet to be exploited since no dedicated synoptic effort has been launched to study various cosmogenic nuclides in the air masses sampled. Seasonal, interannual, and decadal measurements would be required to provide robust transport/mixing and scavenging parameters for development of robust three-dimensional atmospheric models. The task is easily feasible with modern techniques of sampling air and measurements of cosmogenic nuclides.

Cosmogenic Nuclides Produced in the Atmosphere

Cosmic rays are composed of high-energy particles of nuclear matter, accelerated in shockwaves of type II supernovas. Typical energies of nuclei in the primary cosmic ray beam, incident at the top of the atmosphere, lie in the range of 1–10 GeV (1 GeV = 10^9 electron volts). The total energy range is of course much greater, covering 0.1– 10^{11} GeV. Most of the cosmic ray particles have velocities close to that of light and have energies sufficient to break nuclei into fragments. As a comparison, the binding energies of nucleons in nuclei are on the order of 10 MeV. During the passage of cosmic ray particles through the Earth's atmosphere, a nucleonic cascade develops as a result of nuclear interactions of the cosmic rays with atmospheric nuclei. As a result, the cosmic ray beam at depth is composed of a greater number of secondary particles that are capable of inducing further nuclear reactions. A variety of stable and radioactive nuclei are produced in the nuclear interactions of primary and secondary cosmic rays with the atmospheric nuclei N, O, Ar, Kr, and Xe. **Table 1** lists cosmogenic nuclides produced in the Earth's atmosphere that have half-lives exceeding 30 min, which are applied as tracers in earth sciences.

Cosmogenic nuclide production rates are strongly dependent on latitude and altitude in the atmosphere. These rates have been estimated rather accurately, and further attempts are under way to improve these estimates. Estimates have been made of the intensities of slow neutrons in the atmosphere, which allow one to estimate the altitude–latitude dependence of the rates of production of ^{14}C and ^{81}Kr in the atmosphere by the capture of slow neutrons by ^{14}N and ^{80}Kr , respectively. Most other isotopes are produced by high-energy spallation (fragmentation) of nuclei; their rates are approximately

Figure 1 The rate of production of nuclear disintegrations with energy release above 40 MeV is plotted as a function of atmospheric pressure (from Lal and Peters, 1967). To avoid overlapping, curves for different latitudes have been displaced with respect to each other successively by 200 g cm^{-2} along the abscissa. From Lal (1966).

proportional to the rates of nuclear disintegrations, and have been estimated fairly accurately on the basis of measurements of slow neutrons in the atmosphere. **Figure 1** shows the altitude–latitude dependence of the rate of nuclear disintegrations in the atmosphere. For details of (small) departures in the altitude–latitude dependence of nuclide yields from nuclear disintegration rates, refer to Lal (1966) (see [Further Reading](#)). **Figure 1** therefore shows the approximate relative altitude–latitude dependence of all nuclides, except for ^{14}C and ^{81}Kr .

Criteria of Applicability of Cosmogenic Nuclides in Meteorology and Related Sciences

Before discussing the source strengths of cosmogenic nuclides in the atmosphere, and results to date of studies on them, we will briefly review the basis of their application in the study of atmospheric transport and removal processes, and also how one can obtain information about the nature of past atmospheric circulations from observations of the concentrations of these nuclides in continental and oceanic reservoirs.

After their creation in the atmosphere in nuclear interactions, most of the isotopes (**Table 1**) become oxidized; exceptions are ^3He , $^{37,39}\text{Ar}$, and ^{81}Kr . Among the oxides, ^{14}C mixes with the atmospheric CO_2 , whereas others quickly become attached to aerosols (primarily of size $<1 \mu\text{m}$ in diameter). Removal of all nuclides from the atmosphere occurs by radioactive decay and by physical/chemical transfer to other terrestrial reservoirs. In the lower atmosphere, nuclides are removed either by scavenging by droplets formed during condensation, or by gas exchange at air–water interfaces, as applicable for ^3He , $^{37,39}\text{Ar}$, and ^{81}Kr . **Figure 2** is a schematic

Figure 2 Schematic showing the principal avenues of transfer of different cosmogenic nuclides through the atmosphere to different terrestrial reservoirs. A, atmosphere; S, stratosphere; T, troposphere; V, water vapor; B, topsoil and biosphere; M, ocean mixed layer; D, deep sea. V_o and V_c refer to the vapor reservoirs over the ocean and continents, respectively. From Lal (1966).

of different modes of transport of cosmogenic nuclides classified into four principal categories: atmosphere (A), which is subdivided into stratosphere (S), troposphere (T), water vapor (V); topsoil and biosphere (B); ocean mixed layer (M); and deep sea (D).

The flow of tracers through the atmosphere depends on the chemical nature of the elements corresponding to the nuclides; their resulting concentrations depend on their half-lives and the rate constants for exchange/transfer between the reservoirs. The principal application for the cosmogenic nuclides are thus governed primarily by considerations of their expected transfer/flow through the reservoirs, their half-lives, and their chemical natures.

From the above discussion, it follows that, provided cosmogenic nuclides can be measured in the different reservoirs, they should serve as suitable tracers in certain applications. This has been found to be the case. Table 2 lists principal applications of cosmogenic nuclides formed in the atmosphere in nuclear reactions.

Finally, the distributions of the cosmogenic nuclides in the terrestrial reservoirs are expected to depend on the nature of stratospheric-tropospheric exchange and the nature of circulation within the troposphere, and on tropospheric scavenging processes, which are expected to be climate-dependent. Hence, observations of the concentrations of cosmogenic nuclides in the continental and marine sediments and in the polar ice sheets are expected to be indicative of temporal

changes in the nature of large-scale atmospheric circulation in the past.

Production Rates of Cosmogenic Nuclides and Their Inventories in Terrestrial Reservoirs

Table 3 presents estimates of production rates of cosmogenic nuclides with half-lives exceeding 2 weeks, separately for the troposphere, and their global inventory expected to be in secular equilibrium with their production. Table 4 presents production rates of cosmogenic nuclides with half-lives of 30 min to 24 h.

On the basis of the pathways of the nuclides and the inapproximate residence times within the reservoirs versus times for exchange with neighboring reservoirs, their estimated steady-state fractional inventories in the atmosphere and other reservoirs are presented in Table 5. Absolute inventories can be obtained by normalizing the relative inventories by their production rates as given in Table 3. The sources of these nuclides is in the atmosphere, and obviously their absolute inventories in different reservoirs depend critically on the model used for their circulation within the atmosphere and for scavenging from the troposphere. Information on present-day processes and rates can be obtained from current measurements, whereas those for the past have to be based on the concentrations in the polar ice sheets or in continental and marine sediments. Values in Table 5 are therefore useful only as an approximation to the expected values.

Table 2 Important characteristics and principal applications of selected cosmogenic nuclides produced in the atmosphere

Nuclide	Half-life	Application
Isotopes that do not form compounds		
³ He	Stable	Air–sea exchange; escape of helium from the atmosphere
³⁷ Ar	35 days	Atmospheric circulation and air–sea exchange
³⁹ Ar	268 years	Atmospheric circulation; vertical mixing in oceans
⁸¹ Kr	2.3×10^5 years	Ground water ages, and constancy of cosmic radiation
Isotopes that attach to aerosols/particles		
⁷ Be	53 days	Atmospheric circulation, vertical mixing in surface ocean waters
¹⁰ Be	1.5×10^6 years	Atmospheric circulation; role of particle scavenging in the coastal and open oceans; dating of sediments and accretions
²⁶ Al	7.1×10^5 years	Role of particle scavenging in the coastal and open oceans; dating of marine sediments and accretions
³² Si (HSiO ₃ , SiO ₂)	~ 150 years	Atmospheric circulation; labeling the dissolved oceanic silicon pool; atmospheric circulation
³³ P, ³² P	14.3, 25.3 days	Atmospheric circulation; labeling the dissolved oceanic phosphorus pool; tropospheric circulation
³⁹ Cl, ³⁸ S, ³⁸ Cl, ^{34m} Cl, ³¹ Si, ²⁸ Mg, ²⁴ Mg	0.5 h to 21 h	Cloud formation and dissipation, and aerosol scavenging processes by wet precipitation
Isotopes, of half-lives >2 weeks, that label constituent molecules in the atmosphere and the hydrosphere		
³ H (H ₂ O)	12.3 years	Atmospheric circulation; characterizing water molecules in the atmosphere, hydrosphere and cryosphere
¹⁴ C (CO ₂ , CO ₃ , HCO ₃)	5730 years	Atmospheric circulation; characterization of the carbon cycle reservoirs
³² Si (HSiO ₃ , SiO ₂)	~ 150 years	Atmospheric circulation; biogeochemical cycle of silicon
³³ P, ³² P (DIP, DOP)	14.3, 25.3 days	Atmospheric circulation; biogeochemical cycle of phosphorus

DIP and DOP refer to dissolved inorganic and organic phosphorus, respectively.

Table 3 Production rates of cosmogenic nuclides in the Earth's atmosphere, of half-lives exceeding 2 weeks; arranged in order of decreasing half-lives [#]

Isotope	Half-life	Production rate (atoms cm ⁻² s ⁻¹)		
		Troposphere	Total atmosphere	Global inventory
³ He	Stable	6.7×10^{-2}	0.2	3.2×10^3 tons ^d
¹⁰ Be	1.5×10^6 years	1.5×10^{-2}	4.5×10^{-2}	260 tons
²⁶ Al	7.1×10^5 years	3.8×10^{-5}	1.4×10^{-4}	1.1 tons
⁸¹ Kr ^b	2.3×10^5 years	5.2×10^{-7}	1.2×10^{-6}	8.5 kg
³⁶ Cl	3.0×10^5 years	4×10^{-4}	1.1×10^{-3}	15 tons [*]
¹⁴ C	5730 years	1.1	2.5	75 tons
³⁹ Ar ^c	268 years	4.5×10^{-3}	1.3×10^{-2}	52 kg
³² Si	~ 150 years	5.4×10^{-5}	1.6×10^{-4}	0.3 kg
³ H	12.3 years	8.4×10^{-2}	0.25	3.5 kg
²² Na	2.6 years	2.4×10^{-5}	8.6×10^{-5}	1.9 g
³⁵ S	87 days	4.9×10^{-4}	1.4×10^{-3}	4.5 g
⁷ Be	53 days	2.7×10^{-2}	8.1×10^{-2}	3.2 g
³⁷ Ar	35 days	2.8×10^{-4}	8.3×10^{-4}	1.1 g
³³ P	25.3 days	2.2×10^{-4}	6.8×10^{-4}	0.6 g
³² P	14.3 days	2.7×10^{-4}	8.1×10^{-4}	0.4 g

[#]Based on Lal (1966).

^dThe inventory of this stable nuclide is based on its atmospheric inventory, which includes an appreciable contribution from crustal degassing of ³He.

^bBased on the measured atmospheric ⁸¹Kr/Kr ratio of $(5.2 \pm 0.4) \times 10^{-13}$.

^cBased on the measured atmospheric ³⁹Ar/Ar ratio of (0.107 ± 0.004) dpm/liter Ar (STP).

^{*}Includes a rough estimate of ³⁶Cl produced by the capture of neutrons at the Earth's surface.

Observed Distributions of Short-Lived and Long-Lived Cosmogenic Nuclides

Extensive measurements exist of most of the short-lived and long-lived cosmogenic nuclides in all the terrestrial reservoirs where they are found. Relevant to this discussion are the observed concentration of the nuclides in the

atmosphere and their fallout on the Earth, which are governed by the nature of large-scale atmospheric circulation and scavenging processes. It would be beyond the scope of this article to discuss the whole of the data; instead we discuss below some of the highlights to illustrate the scope of cosmogenic tracers.

Table 4 Production rates of several short-lived isotopes produced by cosmic rays in the Earth's atmosphere, of half-lives 30 min–24 h, arranged in order of decreasing half-lives

Isotope	Half-life	Production rate (atoms cm ⁻² s ⁻¹)	
		Troposphere	Total atmosphere
²⁸ Mg	21.2 h	4.6×10^{-5}	1.7×10^{-4}
²⁴ Na	15.0 h	8.2×10^{-5}	3.0×10^{-4}
³⁸ S	2.9 h	1.7×10^{-5}	4.9×10^{-5}

Based on Bhandari *et al.* (1966b) and Lal *et al.* (1968).

The fallout of the short-lived nuclides ³⁵S, ⁷Be, ³³P, and ³²P at latitudes 0–30° is in agreement with their production in the troposphere. The mean scavenging time for the removal of cosmogenic nuclides from the troposphere by dry and wet precipitation is about 30 days, independent of the latitude. This result has been derived using single isotopes as well as pairs of isotopes, such as ⁷Be and ³²P or ³³P and ³²P.

At latitudes of 30–40°, appreciable amounts of stratospheric air mix into the troposphere during spring months, leading to an appreciable enhancement in the concentrations of the nuclides in the air and in wet precipitation. The effect is quite appreciable, and is dramatically supported by observations of a host of fission products released in the stratosphere, which show marked increases in isotope concentrations in air and in wet precipitation at 30–40° latitudes. Stratospheric air builds up to near secular values of concentrations for short-lived isotopes (e.g., ⁷Be and ³²P), corresponding to the higher levels of production rates in the stratosphere (relative to troposphere). When this air descends into the troposphere, the ratios of isotope concentrations in air change dramatically at first for periods comparable to their half-lives (owing to preferential decay of the shorter-lived isotope of a pair), later reaching secular equilibrium values for the troposphere. See, for example, Figure 3, which shows the expected ratios for isotope pairs of ³⁵S, ⁷Be, ³³P, and ³²P.

The fairly extensive measurements of short-lived nuclei in the stratosphere and in the troposphere clearly show their half-life-dependent response to air circulation dynamics. Figure 4 and Figure 5 show measured concentration ratios of ⁷Be and ²²Na/⁷Be, respectively, in the atmosphere. The transport/mixing characteristics clearly show altitude and latitude dependence, as well as seasonal dependence. Detailed measurements of ³²P, ⁷Be, and ²²Na in the same air filters have been presented by Bhandari and colleagues.

Ratios of isotope concentrations are particularly valuable because they are independent of any uncertainties in the volume of air filtered. The observed degree of undersaturation in ²²Na concentrations indicates that the apparent irradiation age of stratospheric air ranges from a few months in the lower layer, just above the tropopause, to ~1–2 years at low latitudes and at altitudes of 18–20 km (Figure 5).

The expected fallout of nuclides that are scavenged by wet precipitation can be deduced fairly accurately from their

estimated production rates in the troposphere and stratosphere (Figure 6), and the observed fallout pattern of ⁹⁰Sr injected in the stratosphere. The resulting distribution is given in Figure 7 for a long-lived nuclide that which does not decay appreciably in the stratosphere.

Constructing Past Histories of Atmospheric Circulation

It seems quite logical to assume that the fallout pattern of cosmogenic isotopes that attach to aerosols would change with changes in the pattern of atmospheric circulation, which in turn would depend on past climates. The paleorecord of this change is partly contained in their concentrations in marine and continental sediments, and in polar ice sheets. This is all one has, to the best of our knowledge, but it is gratifying to see that this record is of a differential type and carries useful information on even high-frequency changes in the atmospheric circulation patterns. As seen from Figure 7, the fallout pattern is latitude-dependent, with varying relative contributions from the troposphere and the stratosphere. Consequently, it should be possible to extract some useful information on any observed paleochange in the fallout of nuclides.

Discussion

We are concerned here with the study of transport and mixing processes within and between the stratosphere and troposphere using tracers, with principal emphasis on cosmic ray-generated nuclides. The injection of radionuclide tracer into the atmosphere as a result of nuclear weapons tests provided fortuitous but valuable information about atmospheric circulation and aerosol scavenging processes, and this directly or indirectly launched similar observations using a variety of other tracers of natural and anthropogenic origin. These include water vapor, carbon dioxide, nitrous oxide, and anthropogenic trace gases: nuclides artificially produced as fission products (e.g., ⁹⁰Sr, and ⁸⁵Kr from weapons tests and due to release from nuclear reactors, respectively), and ¹⁴C produced by capture of weapons-produced neutrons by atmospheric N; and naturally produced radon (²²²Rn) and cosmogenic nuclides. Today we have several atmospheric transport models based on the use of observed distributions of the three categories of tracers to set up and tune three-dimensional models.

Studies of cosmogenic nuclides as atmospheric tracers began soon after the first observations of artificial radionuclides in the atmosphere produced by nuclear weapons tests. This was very fortunate, since aircraft- and balloon-borne programs that were designed specifically to measure fission products released from nuclear weapons tests provided suitable stratospheric and tropospheric air samples for the first measurements of ⁷Be, ³²P, and ²²Na in the atmosphere. These data immediately established the large potential of cosmogenic nuclide as atmospheric tracers.

The value of the cosmogenic radionuclides as tracers lies in the fact that their source functions are fairly well known. This, combined with the fact that several tracers of different chemical properties and half-lives are available, makes them ideally suited for studying spatial and temporal atmospheric

Figure 3 Expected ratios of concentrations (atoms g^{-1} air) of ^{35}S , ^7Be , ^{33}P , and ^{32}P for the hypothetical trajectories of stratospheric air in secular equilibrium, descending in the troposphere. For details see Lal (1966).

processes. Nevertheless, in some respects the transient tracers – those introduced in pulses as a result of test detonation of nuclear weapons – have certain unique advantages that the cosmogenic tracers lack. These include the ability to determine north–south mixing in the equatorial stratosphere, the resulting fallout pattern of nuclides in the troposphere once injected, say, into the equatorial stratosphere, the meridional transport of tracers within the troposphere in the Northern and Southern Hemispheres, and the cross-equatorial transport via the troposphere. The limitations on high accuracy using cosmogenic nuclides arises from the fact that cosmic ray nuclide source functions do not show much latitude dependence in these cases.

The value of transient tracers, is illustrated by two dramatic examples of studies of atmospheric transport rates based on them.

- From combined studies of ^{90}Sr and ^{14}C released in large nuclear weapons tests by the United States and USSR during late 1962, it became possible to determine quantitatively the structure of the troposphere with respect to mixing of air, rates of meridional transport within the two hemispheres, and cross-Equator transport/mixing of air between the two hemispheres. It was shown that the air within the $0\text{--}30^\circ$ and $30\text{--}90^\circ$ tropospheric cells is well mixed on periods of about 1 week, that the meridional mixing within the Northern Hemisphere exhibited a strong seasonal cycle with mean mixing times of 0.5–2.5 months, and that faster mixing occurred during the winter months. It was also determined that the cross-Equator mixing in the troposphere occurred on time scales of 8 ± 3 months.

Figure 4 (a, b) Measured concentrations of ^7Be (in $\text{dpm}/28.3 \text{ m}^3$ STP), in air during two periods of observation in the Northern Hemisphere. The contour lines of equal production rates of ^7Be are given in (Figure 3(c)), (in $\text{dpm}/28.3 \text{ m}^3$ STP), corresponding to the expected ^7Be concentrations for a motionless atmosphere. Thick lines show the position of the tropopause. For details see Lal (1966) and Bhandari *et al.* (1966a).

- Analyses of atmospheric distribution of ^{85}Kr released primarily in the Northern Hemisphere by the nuclear industry suggested a mean time of 1.1 years for the inter-hemispheric exchange time in the troposphere, with little seasonal dependence.

To extract the full value of naturally produced or transient tracers, atmospheric tracers, it is clear that one has to integrate the information obtained from them and realize their limitations and potentials. To fully understand the dynamics of the atmosphere, including transports within and between the stratosphere and the troposphere, one has to integrate the tracer-based information with information on the nature of energy sources and sinks and their temporal and spatial

Figure 5 Measured ratios of activities of ^{22}Na and ^7Be in the atmosphere in a north–south section of the atmosphere. The numbers shown in the figure should be multiplied by 10^{-5} to obtain the absolute activity ratios.

variability. A meteorologist interested in atmospheric dynamics is concerned with numerous atmospheric motion-determining parameters – potential temperature, potential vorticity, generation of large-scale and small-scale waves, their propagation in the stratosphere and troposphere, and so on. Tracer geochemists look at all of this basic physics as locked within ‘black boxes’; they look only at the information on the net space- and time-averaged transport fluxes on the Earth. Clearly, attempts have to be made to bring the two approaches together; limited but successful efforts have been made, as documented in the Further Reading

Except for the detailed studies of several cosmogenic nuclides in the atmosphere during 1955–60, recent studies of ^7Be in the atmosphere, and some isolated studies of ^{36}Cl and ^{10}Be , no dedicated synoptic effort has yet been launched to study many cosmogenic nuclides in the air masses sampled. From the data available to date, however, their potential is clearly borne out for providing robust transport/mixing and scavenging parameters for developing robust three-dimensional atmospheric models. The task is easily feasible with modern techniques of air sampling and measurements of cosmogenic nuclides.

Figure 6 Production rates of nuclear disintegrations and ^{35}S , ^{33}P , and ^{22}Na in an air column with a cross-section of 1 cm^2 plotted against geomagnetic latitude. The lower curves in each figure show the amount produced in the troposphere, the upper curves the total production in the atmosphere. In (a), the dashed curve refers to the total production during 1958, a period of unusually high solar activity. All other curves refer to 1948–49, when solar activity was also quite high. Based on Lal (1966).

Figure 7 The expected pattern of fallout of a long-lived cosmogenic nuclide whose global average production rate is $1 \text{ atom cm}^{-2} \text{ s}^{-1}$ is given by the curve labeled F, curves F_s and F_t give the contributions to fallout from nuclide production in the stratosphere and troposphere, respectively. Based on Lal (1966).

Volcanoes: Composition of Emissions

MT Coffey and JW Hannigan, National Center for Atmospheric Research, Boulder, CO, USA

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

The principal gaseous components of volcanic emissions are water, carbon dioxide, and sulfur (as SO₂, H₂S, and OCS). Only the sulfur gases are significant on a global scale when compared with other natural and anthropogenic sources and represent less than 10% of the input. However, sulfur compounds that reach the stratosphere, when combined with volcanic or meteoric dust particles, are the main precursors of stratospheric aerosols. Those aerosols play a critical role in the regulation of incoming solar radiation and consequently global warming.

Introduction

Volcanic emissions always have been important to the atmosphere of the Earth. Indeed, volcanic and seismic activities are believed to be the source of the initial atmosphere, beginning some 4.6 billion years ago. The principal gaseous components of the early volcanic emissions were, much as they are today, water (H₂O), carbon dioxide (CO₂), nitrogen (N₂), and sulfur (SO₂ and H₂S). The outgassed water condensed to form oceans. CO₂ and the sulfur gases dissolved in the oceans, leaving N₂ as the dominant gas in the atmosphere. Noticeably absent in the emissions is oxygen (O₂), which only appeared some 3.5 billion years ago as organisms developed that could convert CO₂ to organic carbon by photosynthesis thereby producing O₂.

Composition in Magma

Gases comprise approximately 1–4% of the weight of magma ejected by volcanoes. Measurements of the composition of magmatic gases vary widely. Table 1 shows the composition of gases in the magma of a number of major volcanoes. As seen in the table, there can be a wide range of composition, and these values should be considered rather uncertain. The last major eruption was by Mount Pinatubo in 1991. The recent eruption by Eyjafjallajökull in Iceland in April 2010, which was well observed and caused considerable disruption of air travel, was more than an order of magnitude less energetic than the Mount St. Helens (1980) eruption, the least energetic eruption listed in Table 1. Volcanic gas is predominantly water. The second most abundant constituent is CO₂ followed by sulfur gases (SO₂ and H₂S) and hydrogen halides (HBr, HCl, and HF). Smaller

amounts of carbon monoxide (CO), carbonyl sulfide (COS), ammonia (NH₃), hydrogen (H₂), nitrogen (N₂), or other trace gases also may be present.

These gases may react with one another within the magma and the relative composition may change as the magma ascends toward the surface, with an associated change of temperature and pressure. The composition of magmatic gases may also depend on the geologic or tectonic setting of the volcano. Gases emitted from volcanoes at the junction of converging plates have proportionately more H₂O and Cl than gases from divergent plate and hot spot volcanoes. When plates converge, significant amounts of sea water and oceanic crust, rich in H₂O and Cl, can be incorporated into the magma. Hot spots are persistent (10⁷ years or more) areas of hot mantle extrusion at the surface, which may or may not be associated with a plate boundary. The Hawaiian volcanoes are examples of hot spots. The composition of gases emitted by volcanoes may be further modified by interactions near the surface with groundwater systems or local geology.

Clearly, a number of factors may affect the composition of gaseous volcanic emissions, many of which are not well understood. Each volcano must be observed to determine the individual composition of its output.

Volcanic Contribution to Global Sources

Emissions from volcanoes may take the form of a slow, continuous seeping of gas from a vent or fumarole or of an energetic but sporadic eruption. Of the gases listed in Table 1, only the sulfur gases represent a significant contribution by volcanoes to the global budget on an annual basis. It is

Table 1 Gaseous composition of volcanic magma

Volcano year	Magma type	Mass of ejected magma (kg)	Gas composition (volume %)			
			H ₂ O	CO ₂	SO ₂	HCl
Pele 1902	Andesite		80.0	9.0	1.0	0.6
Kilauea 1917	Basalt		79.3	11.6	6.5	0.05
Nyiragongo 1959	Basalt		43.2	40.9	4.4	
Agung 1963	Andesite	2.4 × 10 ¹²	90.0		8.0	1.0
Surtsey 1964	Basalt	2.8 × 10 ¹²	86.1	5.7	2.6	1.0
Mount St. Helens 1980	Andesite	6.5 × 10 ¹¹	91.6	6.6	0.6	
El Chichon 1982	Andesite	1.0 × 10 ¹²	84.0		10.0	1.0
Mount Pinatubo 1991	Andesite	1.0 × 10 ¹⁶	81.6	9.2	4.6	0.3

Table 2 Volcanic contribution to global sources

Gas	Annual volcanic source	Annual natural source (nonvolcanic)	Annual anthropogenic source	Units
H ₂ O	0.0006	423	0.045	Eg H ₂ O yr ⁻¹
CO ₂	0.2	220	35	Pg C yr ⁻¹
H ₂ S, SO ₂	28	229	113	Tg S yr ⁻¹
HCl	0.7	38	6	Tg Cl yr ⁻¹
Hg	0.10	5.2	2.3	Gg Hg yr ⁻¹

estimated that emissions from fumaroles of major volcanoes during quiescent periods may account for more than 10% of the natural sulfur emission. For the other gases, annual emissions are insignificant when compared to other sources, as may be seen in Table 2. In a given year, sulfur emissions during eruptive periods are estimated to contribute less than 1% to the annual, global budget (mostly as H₂S and SO₂). Particular, energetic, sporadic eruptions can, however, represent a significant portion of the annual source for a limited period. The 1991 eruption of Mount Pinatubo was observed to inject a mass of approximately 20 Tg of SO₂ into the atmosphere, approximately 6% of the global annual source for that year. The annual volcanic emission of CO₂ is 100–150 times less than that from human activities.

Eruption Dynamics

The form of a volcanic emission is important in assessing its potential impact on the atmosphere. Gases that are slowly vented at the surface may be efficiently oxidized or removed by rainout. H₂S reacts readily with tropospheric OH and then O₂ to produce SO₂, which eventually ends up as sulfuric acid (H₂SO₄); this is removed in the lower atmosphere by rain. High concentrations of SO₂ may substantially reduce the

lifetime of tropospheric OH, a key reactant in many chemical cycles. HBr contained in volcanic emissions can lead to significant bromine-catalyzed destruction of ozone and mercury within a plume. Hydrochloric acid is very soluble in water and is efficiently removed by rain in the troposphere. Thus, vent emissions may acidify the regional rainfall or have a local polluting effect but have much less consequence on the global scale. Figure 1 shows a diagram of an energetic volcanic eruption. In an energetic eruption, magma and gases are discharged from the vent at high velocity (up to 400 m s⁻¹). Entrainment and heating of the surrounding air cause the plume to rise under the effect of buoyancy. At higher altitudes, the plume reaches a neutral buoyancy level and spreads to form an umbrella-shaped cloud. The maximum height attained by the plume depends largely on the thermal flux at the vent, vent geometry, stratification and moisture content of the atmosphere, and volatile content of the magma.

If the form of the emission is sufficiently explosive and has the appropriate geometry, large quantities of gas and particles may be injected directly into the stratosphere, bypassing tropospheric oxidation and rainout. Once in the stratosphere, the volcanic effluent becomes a global feature due to the rapid east-to-west transport of the region and lack of removal mechanisms. Clear examples of such global volcanic events were the eruptions of El Chichon in 1982 and of Mount Pinatubo in 1991, which each injected large quantities of gas and particles into the stratosphere. Within a few weeks, the plumes of these eruptions encircled the globe and evidence of their effects persisted for many years.

Figure 2 shows the integrated backscatter from a lidar operated at NASA Langley Research Center for the period from 1974 to 2002 and more recent aerosol optical depth observations from three satellite-borne instruments. The backscattered and optical depth signals are an indication of the extent of stratospheric aerosol amount. Signatures of some of the more

recent major volcanic eruptions may be seen in the record. After a period of having a stratosphere as free of aerosols as has occurred since the beginning of these measurements, there now appears to be a slow increase in stratospheric aerosols due possibly to emissions by a number of moderately energetic volcanoes.

Stratospheric Effects

The most important atmospheric effect of volcanoes is probably the introduction of aerosols to the stratosphere. Aerosols are produced by the reaction of gaseous H_2S and SO_2 with water to form aqueous sulfuric acid (H_2SO_4). Sulfuric acid condenses onto solid particles to form stratospheric aerosols. Energetic eruptions also may inject large amounts of solid particles into the stratosphere. These particles are composed

mostly of silicate dust and ash (less than 2 mm diameter). Larger particles fall out of the atmosphere relatively near the vent; smaller particles may remain in the stratosphere for many months as may be seen in Figure 2.

Volcanic aerosols can affect the radiative heating and cooling in the atmosphere. Introduction of H_2SO_4 aerosols into the stratosphere will increase the albedo of the Earth, which is essentially the reflectivity for incoming solar radiation. Sulfate aerosols are efficient scatterers but only weak absorbers at solar wavelengths. Increasing the proportion of solar radiation reflected back to space should cool the atmosphere. The effectiveness of the sulfate aerosols to heat the stratosphere by absorbing outgoing infrared radiation depends on the size of the aerosol. Observations after the eruptions of Agung, El Chichon, and Mount Pinatubo have shown that the lower stratosphere (16–20 km) was warmed by 1–2 K due to the

presence of volcanic aerosols. This topic is discussed further in the article **Climate and Climate Change: Volcanoes: Role in Climate**.

A second important role of volcanic aerosols that are injected into the stratosphere is to serve as sites for heterogeneous reactions which otherwise would not occur. Heterogeneous reactions on sulfate or water aerosols can release chlorine from reservoir species (such as HCl and ClONO₂) and can convert reactive nitrogen species (NO, NO₂, and N₂O₅) into the more stable HNO₃ reservoir. Both these changes enhance the destruction of ozone.

Introduction

The topic of ‘tracers’ is vast, with a rich history that has contributed much to our understanding of the chemistry and dynamics of the atmosphere. A tracer, in the context of atmospheric science, generally refers to a measurable atmospheric species or a parameter that allows one to deduce or infer atmospheric motions and transport, atmospheric chemical reaction pathways, or the magnitude of biogeochemical processes and their influence on the composition of the atmosphere and, hence, on climate. A number of specific tracers are already covered in detail in individual articles in the encyclopedia. The goal of the discussion here is to provide a general overview of the nature and use of measurements of chemical tracers (i.e., chemical species, as opposed to meteorological parameters such as winds, potential temperature, or potential vorticity) to infer the atmospheric circulation and transport of chemical species within and between the stratosphere and troposphere. In many cases, once the influence of transport on chemical species is accounted for, the associated chemical and biogeochemical processes can then be studied.

An Historic Example: The Brewer–Dobson Circulation

A particularly noteworthy and illustrative application of chemical tracers to our fundamental understanding of the circulation of the atmosphere is that of measurements and analysis of the total column ozone by Dobson in the 1920s and 1930s and of stratospheric water vapor and helium by Brewer in the 1940s. Dobson observed that the total amount of ozone measured in the atmospheric column above his ground-based spectrophotometers showed maxima at high latitudes and minima at low latitudes. This dependence on latitude was exactly the opposite of what was expected on the basis of atmospheric chemistry alone, since ozone production is greatest in the upper tropical stratosphere where solar irradiance is most intense. From these observations, Dobson deduced that there must be a global-scale circulation of air from the tropics to high latitudes resulting in the meridional transport of ozone from the tropics to the poles. From the tracers helium and water vapor, Brewer added important vertical information to this picture. The fact that the helium mixing ratio did not change with altitude meant that turbulent transport acted on the stratosphere to prevent gravitational mass fractionation. His observations of very low water vapor mixing ratios in the stratosphere (while studying the formation of condensation trails from aircraft exhaust for defense purposes during World War II) were consistent only with upward transport of air into the stratosphere in the tropics (where the tropopause is high and therefore cold enough to ‘freeze dry’ air as it passed into the stratosphere) and

a downward transport at midlatitudes (where the tropopause is lower and warmer; downwelling would prevent the upward diffusion of wet tropospheric air across the warm extratropical tropopause, which could not freeze dry the air to the observed low stratospheric water vapor levels). This overall picture, derived from chemical tracers, of upwelling in the tropics, meridional transport from the tropics to the poles, and downwelling in the extratropics is known as the Brewer–Dobson circulation. It remains qualitatively correct today. Scientific progress continues through iteration between tracer measurements, dynamical analyses, and chemical–radiative-transport computer models to quantify these rates and to understand the mechanisms driving them. Some of these ‘newer’ efforts using chemical tracers are outlined in the following sections.

Tracers in the Stratosphere

The magnitudes of the mean vertical and meridional winds in the stratosphere are quite small – both in an absolute sense (e.g., $<0.5 \times 10^{-3} \text{ m s}^{-1}$ in the vertical) and in relation to the much faster zonal winds (i.e., around a latitude circle). Thus, they are difficult to measure directly, and tracers must be used to infer these rates and the transport of air that results. These same wind characteristics also make artificial tracer release studies very difficult, as the released material would simply be rapidly redistributed and diluted zonally, yielding little information on vertical and meridional transport, particularly on the time scales of a conceivable tracer release experiment. Thus, we rely on various serendipitous natural or anthropogenic tracers and their time-varying and/or spatially varying characteristics in the troposphere or stratosphere to deduce mean vertical and meridional winds, to understand the efficiency of transport of stratospheric species within and between different regions, such as between the midlatitudes and the polar vortex, for example, and to decouple the effects of transport from the effects of local photochemistry on ozone, for example, once transport has been inferred.

The Morphology and Correlations of Tracer Mixing Ratios in the Stratosphere: CH_4 , N_2O , and CO_2

Methane (CH_4) and nitrous oxide (N_2O) are produced primarily through biological processes in the troposphere and are destroyed by photolysis and photochemistry in the stratosphere on time scales from many years to months, depending on altitude. Observations from satellites have provided a global-scale picture of the distribution of their mixing ratios throughout the stratosphere (Figure 1). The morphologies of their mixing ratio contours share a common shape. The common shape can be understood qualitatively in terms of the

Figure 1 Stratospheric mixing ratios of (a) CH_4 and (b) N_2O versus latitude and pressure–altitude measured on 25 September 1992 from the CLAES instrument aboard the Upper Atmosphere Research Satellite. Brewer–Dobson circulation combined with rapid quasi-horizontal transport and mixing of air induced by the breaking of planetary-scale waves at midlatitudes, as illustrated in Figure 2. Upwelling of air that recently entered the stratosphere from the troposphere in the tropics (with correspondingly high values of CH_4 and N_2O) couples with downwelling of older, photochemically processed air from the upper stratosphere (with low levels of CH_4 and N_2O) at middle and high latitudes to form a ‘bulge’ of high mixing ratio contours (also known as ‘isopleths’) in the tropics. Rapid quasi-horizontal transport and mixing of air between the tropics and extratropics along isentropic surfaces serves to flatten this bulge. Thus, the slope of the isopleths at midlatitudes is controlled by the relative rates of vertical advection (which steepens the isopleths) and quasi-horizontal diffusion (which flattens the isopleths). Relatively rapid changes in slope with latitude separate regions where the dominant transport mechanisms are different, such as between the tropics and the

midlatitudes (where the so-called subtropical boundary indicates a transition between upwelling in the tropics and rapid quasi-horizontal transport in the so-called midlatitude ‘surf zone’) and between the midlatitude surf zone and the polar vortices (where transport across the wind maximum at the vortex edge is limited). Consequently, the magnitudes of the isopleth slopes and their dependence on latitude and how these properties change with season, latitude, and altitude provide important information on transport and details of the underlying dynamics, as well as diagnostics for models.

In addition, theory dictates that any chemical tracers that are long-lived with respect to both vertical and horizontal transports in a region of the stratosphere will share a common morphology in that region. Thus, a plot of simultaneous measurements of one long-lived tracer versus another will yield what is known as a ‘compact’ or tight relationship for which one tracer mixing ratio is well predicted if the other is known. The species are said to be in slope equilibrium. If horizontal

Figure 2 Schematic representations of (a) stratospheric transport for which quasi-horizontal transport (diffusion) is globally effective, (b) the resulting tracer isopleths (surfaces of constant mixing ratio), and (c) the resulting tracer–tracer correlation for tracers that are long-lived with respect to both vertical and horizontal transport rates.

transport is fast and effective globally, then the long-lived tracer isopleths and the tracer–tracer relationships are globally uniform (Figure 2). If horizontal transport from the midlatitudes into the tropics is restricted, the isopleths and the resulting tracer–tracer correlations are different in these different regions (Figure 3). Simultaneous observations of tracer–tracer correlations measured from satellite, balloon, and aircraft instruments in the 1990s (including CH_4 , N_2O , CFCs, O_3 , NO_x , and CO_2 measurements) revealed that the real atmosphere lies somewhere between the two conceptual

Figure 3 Schematic representations of (a) stratospheric transport for which quasi-horizontal transport from the extratropics into the tropics is slow, (b) the resulting tracer isopleths, and (c) the resulting tracer–tracer correlations.

extremes in Figures 2 and 3. Observed tracer correlations are indeed compact but different in the tropics and extratropics, demonstrating that horizontal transport from midlatitudes into and across the tropics is not rapid enough to result in globally uniform correlations. However, analyses of the correlations indicate that a significant amount of older air from midlatitudes does mix back into the tropical upwelling region at altitudes between the tropopause and about 21 km. Besides being of fundamental interest, knowledge of the degree to which midlatitude air ‘recirculates’ into the tropics is critical for

predicting pollutant build-up in the stratosphere and its redistribution, such as exhaust from a future fleet of commercial supersonic aircraft that would fly at about 20 km mostly in the midlatitudes.

Plotting one long-lived tracer against another also serves another important function: it removes the variability in stratospheric tracer measurements associated with large-scale reversible air displacements and, to some extent, with irreversible mixing. The spatial variability these processes induce on tracer mixing ratios can make it difficult to interpret tracer measurements along an aircraft flight track, for example, and to compare them with numerical model predictions. Simultaneous measurements of CO_2 and N_2O from the NASA ER-2 aircraft illustrate both this simplification and the determination of relative transport rates discussed above. CO_2 is a conserved tracer in the stratosphere; its mixing ratio in air entering the tropical stratosphere exhibits both a long-term increase due to anthropogenic activities and an annual cycle due to the seasonal uptake and release of carbon by the terrestrial biosphere (Figure 4). These variations forced from the troposphere propagate into the stratosphere. In the tropics, the vertical propagation of the maxima and minima of the CO_2 seasonal cycle from the tropopause is easily discernible when the observed CO_2 mixing ratio is plotted against potential temperature (Figure 5(a)). As discussed further below, the preservation of the seasonal cycle in the

Figure 4 Observations of stratospheric CO_2 . Asterisks are measured CO_2 mixing ratios at the tropical tropopause or in air that has recently entered the stratosphere based on simultaneous measurements of other tracers. Upper curve: Continuous boundary condition for CO_2 mixing ratios entering the stratosphere based on surface measurements from the NOAA Climate Monitoring and Diagnostics Laboratory Cooperative Air Sampling Network, which accounts for seasonal and interannual variations in the CO_2 growth rate. The long-dashed line is a linear fit to the continuous boundary condition. Lower curve (see text): The solid line has the same slope as the linearized boundary condition above but with a time lag of 4.5 years; short dashed lines correspond to delays of 4 and 5 years. Filled circles are balloon measurements of CO_2 made in the mid-latitude stratosphere between about 20–25 and 30 km (a region of near-constant CO_2 mixing ratio) and triangles are aircraft measurements corresponding to N_2O values of 110 ppb, revealing a consistency in mean ages in this region of the stratosphere that dates back to the 1970s. Adapted from Andrews A.E., et al., 2001. Mean ages of stratospheric air from in situ observations of CO_2 , CH_4 , and N_2O . *Journal of Geophysical Research* 106 (D23), 32295–32314. Copyright 2001 American Geophysical Union.

Figure 5 (a) Observations of CO_2 from the NASA ER-2 aircraft in the tropics versus potential temperature. The tropopause is at 390 K. (b) CO_2 versus potential temperature in the extratropics in November 1995. (c) CO_2 versus N_2O in the extratropics (gray) and the tropics (black) in November 1995; inset are the CO_2 observations binned and averaged as a function of N_2O in these two regions. tropics indicates that vertical advection dominates both vertical diffusion and the mixing in of older air from the extratropics in this region of the stratosphere. At midlatitudes, however, a plot of CO₂ mixing ratio against potential temperature is highly scattered (Figure 5(b)). Plotting CO₂ versus another long-lived tracer, such as N₂O, gives a striking compact relationship (Figure 5(c)). From this compact relationship, we can infer that quasi-horizontal transport in the extratropics is rapid compared to the chemical lifetime of N₂O and to the rate of seasonal changes in the CO₂ mixing ratio at the tropical tropopause. Moreover, because the CO₂:N₂O tracer correlation in the tropics is distinguishable from that in the extratropics (Figure 5(c)), quasi-horizontal transport across the tropics is not efficient enough to result in a globally uniform CO₂:N₂O relationship. The observed attenuation of the CO₂ seasonal cycle in the tropics, however, does indicate that a significant amount of extratropical air has been mixed into the tropical upwelling region, with 30–50% of the air at 19 km of midlatitude origin.

Temporally Increasing Inert Tracers: CO₂ and SF₆

Species that are increasing over time in the troposphere due to anthropogenic activities but that are inert in the stratosphere have been used to infer the mean age of air at various locations and times in the stratosphere. The mean age is the average time since the air for which CO₂ or SF₆ is measured was in contact with the troposphere. A boundary condition for CO₂ or SF₆ mixing ratios at the tropical tropopause, where air predominantly enters the stratosphere, is needed to derive accurate mean ages (e.g., Figure 4). The mean age of an air parcel can be approximated from the time delay between the mixing ratio observed (or inferred) at the tropopause and the mixing ratio measured in the air parcel. From a series of measurements during the 1990s from aircraft and balloon instruments, precise and accurate mean ages have been derived for air over a wide range of latitudes and altitudes (± 0.3 and ± 0.5 years, respectively, for ages derived from CO₂ measurements once the seasonal cycle has damped out at a mean age of ~ 2 years). These mean ages are also consistent with those derived from balloon observations of CO₂ dating back to the 1970s now that a robust boundary condition for CO₂ entering the stratosphere, based on the extensive NASA ER-2 CO₂ observations, can be parameterized from surface CO₂ measurements for those years (e.g., Figure 4). As expected from the Brewer–Dobson circulation, the youngest air is observed just above the tropical tropopause, with age increasing with altitude and latitude to a maximum of about 6 years. Knowledge of the mean ages helps define relative vertical and horizontal transport rates in different regions of the atmosphere and the turnover time for the stratosphere with respect to exchange of air with the troposphere. Mean ages from inert tracers are also serving as quantitative tests of transport, independent of photochemistry, for two- and three-dimensional models of the stratosphere. As of 1998 when the mean ages inferred from CO₂ and SF₆ observations were well-established, most two- and three-dimensional models were underestimating mean ages by 20–100%.

Seasonally Varying Tracers: H₂O, CO₂

Species that enter the stratosphere with a pronounced annual cycle in their mixing ratios have been used to infer vertical ascent rates in the tropics, vertical diffusion in the tropics, and the rates at which air is transported quasi-horizontally between the tropics and midlatitudes. Observations of CO₂ were discussed in the preceding section. Water vapor mixing ratios entering the stratosphere also exhibit an annual cycle, which is in phase with the annual cycle in tropopause temperatures. Exactly what dynamical and/or microphysical processes control the saturation mixing ratios in the tropopause region, however, is still hotly debated; apparently, Brewer's simple freeze-drying mechanism at the tropopause is not sufficient. From observations of the vertical propagation of the seasonal cycles of CO₂ and water vapor from the tropopause (e.g., Figure 5(a)), vertical ascent rates can be derived. The observed attenuations of the seasonal amplitudes with altitude effectively give the rate of horizontal transport of older air from midlatitudes (since vertical diffusion is known to be small from other observations), as noted above for CO₂. Observations of seasonal variations at midlatitudes yield information on quasi-horizontal transport rates out of the tropics. Continuous monitoring of stratospheric water vapor from the tropopause to the stratopause has been achieved through satellite measurements that have a vertical resolution of 1–3 km. The satellite observations show the propagation of the water vapor seasonal cycle to about 28 km before it is damped out. The *in situ* aircraft CO₂ observations are not continuous in time but have high vertical resolution (~ 10 m) in the near-tropopause region between 16 and 20 km where air is entering the stratosphere and the mixing in of midlatitude air is the most rapid. Thus, the CO₂ and H₂O measurements are highly complementary. Interestingly, these two tracers both yield relatively precise seasonally resolved vertical ascent rates that are nearly identical to those derived from calculations of the meridional circulation estimated from heating rates computed with radiative transfer models using satellite and/or climatological data for species active in the infrared. The calculations of radiative heating in the lower tropical stratosphere have large uncertainties because the net heating rates are small, being the difference between two large numbers.

Anthropogenic 'Pulsed' Tracers: Bomb Debris from Atmospheric Nuclear Testing

It was noted above that the release of artificial tracers to study stratospheric transport is not readily feasible, in part owing to the prohibitive magnitude of material that would have to be released. However, the massive amount of material injected into or produced in the stratosphere by atmospheric nuclear testing in the late 1950s and early 1960s served as a 'pulsed' input of radioactive tracers into the stratosphere. Transport within and out of the stratosphere can be followed from observations of tritiated water vapor (HTO), ¹⁴CO₂, and fission products, such as ⁹⁰Sr, that were made from aircraft and balloons from that time until as recently as 1983 for HTO. In particular, observations over a number of years of gaseous ¹⁴CO₂ and of ⁹⁰Sr and other fission products scavenged by aerosol were used to study transport within the stratosphere. For several decades, the ¹⁴CO₂ data were considered unreliable

and too sparse to be useful, at least in part because virtually all atmospheric models of the time dispersed and removed the $^{14}\text{CO}_2$ faster than was consistent with the observations. However, with the problems that contemporary models have had in calculating mean ages of air that are too young compared with those derived from CO_2 and SF_6 , coupled with recent observations of the slow dispersal of sulfuric acid aerosol from the Mt. Pinatubo eruption out of the tropics at altitudes greater than 22 km (see below), the data are now considered less suspect and are undergoing a renaissance of re-examination and comparisons with model predictions. In particular, the pulsed nature of this tracer is complementary to the continuous input of long-lived tracers with tropospheric sources, such as CO_2 , N_2O , CH_4 , and SF_6 noted above. A recent reanalysis of HTO measurements shows an interesting decay that is longer than the oldest mean ages or residence times for stratospheric air, which has been interpreted as the eigentime of the longest-lived mode of the stratospheric transport equations. Thus, even older data that were once thought to be suspect or too sparse to be compared with model results are being reanalyzed and reinterpreted using new insights as our understanding of stratospheric dynamics and tracer transport evolves.

A Natural 'Pulsed' Tracer: Sulfur from the Mt. Pinatubo Eruption

In June 1991, Mt. Pinatubo in the Philippines erupted, injecting tons of SO_2 into the tropical stratosphere. The SO_2 was rapidly oxidized to H_2SO_4 and resulted in sulfate aerosol concentrations 30 times higher than the nonvolcanic background levels. Because this material entered the tropics, its transport via the stratospheric circulation could be followed by satellite, balloon, aircraft, and ground-based aerosol measurements. Observations showed the rate of transport quasi-horizontally out to midlatitudes as a function of altitude. Transport out of the 'tropical reservoir' (so-called because the tropics acted to 'contain' the aerosol for a significant amount of time) to midlatitudes was rapid below altitudes of 22 km but very slow between 22 and 28 km, suggesting, as did the satellite water vapor data mentioned above, a relatively isolated region at $\sim 22\text{--}28$ km where transport was solely by vertical advection with little or no input of air from midlatitudes and only episodic and occasional transport from the tropical region out to midlatitudes.

Other Tracers in the Stratosphere: Cosmogenic Radionuclides and Stable Isotopes

Although a number of pioneering observations of cosmogenic radionuclides and stable isotope compositions of long-lived tracers were made, in both cases relatively new mass spectrometric techniques have been developed that make their measurement in the stratosphere both more practical and more compelling for the study of stratospheric transport processes in the future. They include continuous-flow isotope ratio mass spectrometry for stable isotopic analyses, which requires orders of magnitude smaller whole air sample sizes, and accelerator mass spectrometry, which allows precise ^{10}Be measurements to be made in conjunction with ^7Be to obtain the $^{10}\text{Be}/^7\text{Be}$ ratio, a more robust tracer than ^7Be alone.

Cosmogenic Radionuclides

^{10}Be and ^7Be are produced in the lower stratosphere and upper troposphere by cosmic ray-induced spallation reactions involving nitrogen and oxygen (e.g., $^{16}\text{O}(\text{n},4\text{p}3\text{n})^{10}\text{Be}$). Peak production rates occur at approximately 16–20 km at midlatitudes. Once formed, the ^{10}Be and ^7Be atoms are scavenged by aerosol particles and decay with half-lives of 1.6×10^6 years and 53 days, respectively. In the stratosphere, where submicrometer aerosol residence times are quite long, the ratio of $^{10}\text{Be}/^7\text{Be}$ will increase over time as the ^7Be decays rapidly relative to ^{10}Be . In the troposphere, however, aerosol residence times are short (on the order of 20–40 days), preventing the ratio of $^{10}\text{Be}/^7\text{Be}$ from increasing substantially above the production ratio. Thus, owing to this difference in aerosol residence times, the $^{10}\text{Be}/^7\text{Be}$ ratio can increase significantly above the production ratio only in the stratosphere, and the ratio represents an 'age' since the air mass was last cleansed of its beryllium atoms. In general, then, the distribution of ^{10}Be and ^7Be production in the atmosphere and the 'clock' provided by the difference in their half-lives make observations of the ratio useful for the study of both meridional and diffusive transport processes in the stratosphere and stratosphere–troposphere exchange on time scales of several months to several years. To date, however, there are fewer than 50 published observations of stratospheric $^{10}\text{Be}/^7\text{Be}$ ratios.

Stable Isotopes

Rates of chemical reactions often depend on whether the molecule possesses a heavy or light isotope; the difference in rates, for example, between the reactions $^{13}\text{CH}_4 + \text{Cl}$ and $^{12}\text{CH}_4 + \text{Cl}$ is called an isotope effect and is large at stratospheric temperatures ($\text{rate}(^{12}\text{CH}_4)/\text{rate}(^{13}\text{CH}_4)1.075$ at 223 K). Thus, as CH_4 is oxidized in the stratosphere, the remaining CH_4 becomes progressively enriched in ^{13}C . While the carbon isotopic composition of CH_4 is in some respects just another long-lived tracer, its correlation with CH_4 mixing ratios depends sensitively on transport while its sensitivity to, for example, modeled photochemistry should be the same for $^{13}\text{CH}_4$ as for $^{12}\text{CH}_4$ in a given model. Therefore, stable isotope compositions for CH_4 , N_2O , and CO_2 and other species may provide additional constraints on stratospheric photochemistry and transport in different regions of the stratosphere now that global-scale measurements are becoming more feasible.

Tracers of Stratosphere–Troposphere Exchange

Understanding the rates, patterns, and underlying dynamics of mass exchange between the troposphere and stratosphere has significant implications for chemistry in both regions and for predicting how these characteristics may change as climate changes. Tracers used to investigate troposphere-to-stratosphere transport have included CO_2 and water vapor mixing ratios, short-lived chemical species in the troposphere such as CHBr_3 , and ^{222}Rn , a radionuclide with a half-life of 3.8 days derived from crustal rocks and soils. Tracers used to investigate stratosphere-to-troposphere transport have included cosmogenic radionuclides and fission products from atmospheric nuclear testing.

Troposphere-To-Stratosphere Transport

From the seasonally resolved vertical ascent rates just above the tropical tropopause inferred from the water vapor and CO₂ observations discussed above, mass fluxes into the stratosphere can be calculated. In addition, the stratospheric CO₂ observations show that air entering the tropical stratosphere throughout the year is characteristic of the upper tropical troposphere, as opposed to air at any given surface site from either hemisphere being injected directly by convective systems without extensive mixing along the way. This analysis is predicated on the fact that CO₂ variations in the troposphere vary dramatically with latitude and altitude. Water vapor is a powerful tracer of details of troposphere-to-stratosphere transport since its saturation mixing ratio is very sensitive to the pathway and timing of entry. Dynamical and microphysical mechanisms that quantitatively explain stratospheric dryness are still being sought, however.

New measurements of the isotopic composition of water vapor entering the tropical stratosphere may shed further light on the dehydration mechanism(s), since the relative abundances of deuterium and ¹⁸O in upper tropospheric and lower stratospheric water vapor are very sensitive to the dehydration process. For example, models of slow vertical ascent into the stratosphere yield isotopic values very different from those from models of dehydration (and rehydration) in convective systems reaching or penetrating the tropopause.

Measurements of very short-lived chemical species, such as CHBr₃ (with a global lifetime of 0.1 years) or radioactive tracers with fast decay rates, such as ²²²Rn (with a half-life of 3.8 days) above and below the tropopause have also been pursued in order to provide information on rates of transport of air from the surface to the upper troposphere and the lower stratosphere. Significant vertical gradients exist for these species in the troposphere, as expected from their short lifetimes and surface sources. High spatial and temporal variability is observed in the upper troposphere, with higher mixing ratios or activities observed after recent convective events. Sporadic observations of such short-lived species have been made just above the tropical tropopause, but quantifying the average time scale for input of air across the tropical tropopause and its mechanism (i.e., slow vertical ascent or rapid overshooting convection) or determining from what characteristic altitude region the air comes from has so far remained elusive. In addition, tracers have also been used to test the degree and nature of transport of air across the extratropical tropopause. Studies using observations of CO₂, water vapor, and other tracers, for example, are based on the dependence of these tracers' concentrations with latitude of entry of air: CO₂ varies with latitude owing to the surface distribution of its sources and sinks, and water vapor varies owing to the variation of tropopause temperature with latitude. To date, these measurements have shown that diabatic transport across the midlatitude tropopause is minimal and that isentropic transport from the tropical/subtropical upper troposphere affects stratospheric composition only in the lowermost stratosphere (defined as the region below 380 K potential temperature).

Stratosphere-To-Troposphere Transport

Because most of the production of cosmogenic beryllium nuclides occurs in the stratosphere, ⁷Be has been used as

a qualitative tracer of stratosphere-to-troposphere transport. Measurement of the ¹⁰Be/⁷Be ratio is now preferred, however, since sampling errors cancel out and isotope fractionation does not occur during aerosol removal processes, such as gravitational settling in the stratosphere or wet and dry deposition in the troposphere. Thus, even if only a small fraction of beryllium atoms remain in sampled air, the ratio still retains its 'age' or stratospheric signature. For example, air samples collected weekly at the surface in the Arctic at Alert, Canada, and in some high-latitude upper tropospheric samples showed low ⁷Be concentrations that alone might have suggested no stratospheric influence; however, they have frequently corresponded to high ¹⁰Be/⁷Be ratios, which can only have come from the stratosphere. Estimates of stratospheric input of air to the Arctic lower troposphere of a few percent have been made from 1 year of ground-based observations. Other important tracers of the timing and magnitude of stratosphere-to-troposphere transport are the large data sets of fission products and tritium detected in tropospheric precipitation after the atmospheric nuclear bomb tests. These data show that transport from the stratosphere to the Northern Hemisphere maximizes during northern spring, even though the maximum mass flux into the stratosphere occurs December through February. The fact that the maximum mass flux out of the stratosphere occurs several months after the maximum mass flux in is consistent with the fact that the lowermost stratosphere grows in mass from December to March.

Tracers in the Troposphere

For comparison with the stratospheric and stratosphere-troposphere exchange tracers discussed above, several examples of tracer studies in the troposphere are briefly outlined here. Gradients in the mixing ratios of tracers such as CO₂ that have major sources in the Northern Hemisphere are used to constrain the rate of interhemispheric transport for air at the surface to about 1 year. The disappearance of these gradients in the upper troposphere indicates that air is efficiently mixed between the hemispheres in the intertropical convergence zone. Vertical transport has been investigated, for example, using the short-lived radioactive tracer ²²²Rn and its daughter product ²¹⁰Pb as well as the attenuation of the CO₂ annual cycle in the upper troposphere with respect to the surface. Simultaneous measurements of a set of chemical species with varying photochemical lifetimes have also been used in tropospheric studies, somewhat analogously to the CH₄:N₂O:CFC correlations in the stratosphere but operative on smaller spatial and temporal scales. For example, the ratios of alkanes in an air mass can be used to estimate the age of an industrial plume, since the ratios of the alkane concentrations change as the air mass ages due to their different reaction rates with OH. Tracer release studies are difficult in the troposphere as well as in the stratosphere. Small-scale releases of SF₆ have been used for studies of urban pollution dispersion and of vertical transport within a convective system. Larger-scale tracer release experiments are difficult in part due to the large mass of the troposphere. One attempt to overcome this difficulty was the release in 1984 of fully deuterated methane, ¹³CD₄ and ¹²CD₄, at an altitude of 5 km between Christchurch, New Zealand, and Antarctica, followed by collection of air from

aircraft and ground-based stations for analysis of the isotope ratios with respect to $^{12}\text{CH}_4$. Because the analysis could detect as little as two parts of tracer in 10^{17} parts of air against an essentially zero background, tracer could be detected in surface and mid-troposphere samples from 1 day to more than 3 weeks after the release. Some limited information was derived on tropospheric relative diffusion rates to hemispheric scales from this unique experiment.

DEDICATION

This second edition of the *Encyclopedia of Atmospheric Sciences* is dedicated to the memory of James Holton who was editor-in-chief of the first edition. He was a great researcher and colleague inspiring an entire generation of atmospheric scientists.

CONTENTS

<i>List of Contributors</i>	xxvii
<i>Preface to the First Edition</i>	xxxix
<i>Preface to the Second Edition</i>	xli
<i>Editor Biographies</i>	xliii
<i>Guide to Using the Encyclopedia</i>	xlvi

VOLUME 1

BASIC ATMOSPHERIC STRUCTURE AND CONCEPTS	1
Beaufort Wind Scale	1
<i>L Hasse</i>	
Wind Chill	7
<i>M Bluestein</i>	
Standard Atmosphere	12
<i>W W Vaughan</i>	
AEROSOLS	17
Aerosol–Cloud Interactions and Their Radiative Forcing	17
<i>U Lohmann</i>	
Aerosol Physics and Chemistry	23
<i>M Kalberer</i>	
Climatology of Stratospheric Aerosols	32
<i>L W Thomason and J-P Vernier</i>	
Climatology of Tropospheric Aerosols	40
<i>N Bellouin and J Haywood</i>	
Dust	48
<i>I N Sokolik</i>	
Observations and Measurements	53
<i>P H McMurry</i>	
Role in Radiative Transfer	66
<i>G A Ban-Weiss, and W D Collins</i>	

Role in Climate Change <i>N Bellouin</i>	76
Soot <i>P Chylek, S G Jennings, and R Pinnick</i>	86
Agricultural Meteorology and Climatology <i>E S Takle</i>	92
ARCTIC AND ANTARCTIC	98
Antarctic Climate <i>J Turner</i>	98
Arctic Climate <i>M C Serreze</i>	107
Arctic Haze <i>L M Russell and G E Shaw</i>	116
AIR SEA INTERACTIONS	
Freshwater Flux <i>J Schulz</i>	122
Momentum, Heat, and Vapor Fluxes <i>P K Taylor</i>	129
Sea Surface Temperature <i>W J Emery</i>	136
Surface Waves <i>A Benilov</i>	144
AVIATION METEOROLOGY	153
Aircraft Emissions <i>R R Friedl</i>	153
Aircraft Icing <i>M K Politovich</i>	160
Aviation Weather Hazards <i>A J Bedard, Jr</i>	166
Clear Air Turbulence <i>G P Ellrod (Retired), J A Knox, P F Lester, and L J Ehernberger (Retired)</i>	177
BIOGEOCHEMICAL CYCLES	187
Sulfur Cycle <i>P Brimblecombe</i>	187
Bromine <i>R von Glasow and C Hughes</i>	194
Heavy Metals <i>T D Jickells and A R Baker</i>	201

Iodine	205
<i>L J Carpenter</i>	
BOUNDARY LAYER (ATMOSPHERIC) AND AIR POLLUTION	220
Overview	220
<i>P J Mason and D J Thomson</i>	
Air Pollution Meteorology	227
<i>X-M Hu</i>	
Coherent Structures	237
<i>F T M Nieuwstadt and J C R Hunt</i>	
Complex Terrain	242
<i>J J Finnigan</i>	
Convective Boundary Layer	250
<i>M A LeMone</i>	
Microclimate	258
<i>M W Rotach and P Calanca</i>	
Modeling and Parameterization	265
<i>A A M Holtslag</i>	
Observational Techniques <i>In Situ</i>	274
<i>E F Bradley</i>	
Observational Techniques: Remote	284
<i>W M Angevine and C J Senff</i>	
Ocean Mixed Layer	290
<i>L Kantha and C A Clayson</i>	
Stably Stratified Boundary Layer	299
<i>L Mahrt</i>	
Surface Layer	305
<i>G L Geernaert</i>	
Urban Heat Islands	310
<i>J C Luvall, D A Quattrochi, D L Rickman, and M G Estes, Jr</i>	
Diurnal Cycle	319
<i>A Betts</i>	
CHEMISTRY OF THE ATMOSPHERE	324
Chemical Kinetics	324
<i>R P Wayne</i>	
Ion Chemistry	333
<i>J L Fox</i>	
Isotopes, Stable	348
<i>C A M Brenninkmeijer</i>	
Laboratory Kinetics	356
<i>D J Donaldson and S N Wren</i>	

Methane <i>E Dlugokencky, and S Houweling</i>	363
Observations for Chemistry (<i>In Situ</i>): Ozone Sonde <i>H G J Smit</i>	372
Observations for Chemistry (<i>In Situ</i>): Particles <i>T Deshler</i>	379
Observations for Chemistry (<i>In Situ</i>): Water Vapor Sonde <i>J B Smith</i>	387
Observations for Chemistry (Remote Sensing): IR/FIR (Satellite, Balloon and Ground) <i>H Fischer and F Hase</i>	401
Observations for Chemistry (Remote Sensing): Lidar <i>G Vaughan</i>	411
Observations for Chemistry (Remote Sensing): Microwave <i>J Waters</i>	418
Principles of Chemical Change <i>R P Wayne</i>	429
Radioactivity: Cosmogenic Radionuclides <i>D Lal</i>	437
Volcanoes: Composition of Emissions <i>M T Coffey and J W Hannigan</i>	446
Tracers <i>K A Boering</i>	450

VOLUME 2

CLIMATE AND CLIMATE CHANGE	1
Overview <i>D L Hartmann</i>	1
Carbon Dioxide <i>C L Sabine and R A Feely</i>	10
Climate Feedbacks <i>A E Dessler and M D Zelinka</i>	18
Climate Prediction: Empirical and Numerical <i>S Hastenrath</i>	26
Climate Variability: Decadal to Centennial Variability <i>D G Martinson</i>	33
Climate Variability: Nonlinear and Random Effects <i>M Ghil</i>	38
Climate Variability: North Atlantic and Arctic Oscillation <i>J W Hurrell</i>	47
Climate Variability: Seasonal and Interannual Variability <i>D S Gutzler</i>	61

Energy Balance Climate Models <i>G R North and K-Y Kim</i>	69
Global Impacts of the Madden–Julian Oscillation <i>C Zhang</i>	73
Greenhouse Effect <i>G R North</i>	80
History of Scientific Work on Climate Change <i>S Weart</i>	87
Intergovernmental Panel on Climate Change <i>K E Trenberth</i>	90
Nuclear Winter <i>A Robock</i>	95
Radiative–Convective Equilibrium Climate Models <i>N O Renno and X Huang</i>	102
Volcanoes: Role in Climate <i>A Robock</i>	105
CLOUDS AND FOG	112
Cloud Modeling <i>W-K Tao and M Moncrieff</i>	112
Contrails <i>P Minnis</i>	121
Cloud Microphysics <i>D Lamb</i>	133
Classification of Clouds <i>A L Rangno (Retiree)</i>	141
Climatology <i>S Warren, R Eastman, and C J Hahn</i>	161
Measurement Techniques <i>In situ</i> <i>D Baumgardner, J-F Gayet, A Korolev, C Twohy, and J Fugal</i>	170
Fog <i>P J Croft and B Ward</i>	180
Noctilucent Clouds <i>G E Thomas</i>	189
Stratus and Stratocumulus <i>R Wood</i>	196
CRYOSPHERE	201
Glaciers, Topography, and Climate <i>A B G Bush and M P Bishop</i>	201
Permafrost <i>T E Osterkamp and C R Burn</i>	208

Sea Ice	217
<i>M C Serreze, F Fetterer, and W F Weeks (Retired)</i>	
Snow (Surface)	227
<i>M Sturm</i>	
DATA ASSIMILATION AND PREDICTABILITY	237
Data Assimilation	237
<i>A C Lorenc</i>	
Ensemble-Based Data Assimilation	241
<i>Z Meng and F Zhang</i>	
Ensemble Prediction	248
<i>R Buizza</i>	
Predictability and Chaos	258
<i>L A Smith</i>	
DYNAMICAL METEOROLOGY	265
Overview	265
<i>J R Holton</i>	
Acoustic Waves	272
<i>K E Gilbert</i>	
Atmospheric Tides	287
<i>J Oberheide, M E Hagan, A D Richmond, and J M Forbes</i>	
Balanced Flow	298
<i>M E McIntyre</i>	
Baroclinic Instability	304
<i>R Grotjahn</i>	
Coriolis Force	313
<i>D W Moore</i>	
Critical Layers	317
<i>P Haynes</i>	
Hamiltonian Dynamics	324
<i>T G Shepherd</i>	
Hydraulic Flow	332
<i>R B Smith</i>	
Inertial Instability	334
<i>J A Knox</i>	
Kelvin–Helmholtz Instability	343
<i>P G Drazin</i>	
Kelvin Waves	347
<i>B Wang</i>	
Kinematics	353
<i>D D Houghton</i>	

Laboratory Geophysical Fluid Dynamics <i>R L Pfeffer</i>	360
Lagrangian Dynamics <i>I Roulstone</i>	369
Potential Vorticity <i>M E McIntyre</i>	375
Primitive Equations <i>A A White and N Wood</i>	384
Quasigeostrophic Theory <i>H C Davies and H Wernli</i>	393
Rossby Waves <i>P B Rhines</i>	404
Solitary Waves <i>J P Boyd</i>	417
Static Stability <i>J A Young</i>	423
Stationary Waves (Orographic and Thermally Forced) <i>S Nigam and E DeWeaver</i>	431
Symmetric Stability <i>H B Bluestein</i>	446
Vorticity <i>J R Holton</i>	451
Wave-CISK <i>C S Bretherton</i>	455
Wave Mean-Flow Interaction <i>M Juckes</i>	458
Waves <i>J R Holton</i>	464

VOLUME 3

ELECTRICITY IN THE ATMOSPHERE	1
Global Electrical Circuit <i>E R Williams</i>	1
Ions in the Atmosphere <i>K L Aplin and R G Harrison</i>	9
Lightning <i>M B Baker</i>	14
Sprites <i>W A Lyons</i>	20
Forensic Meteorology <i>L E Branscome</i>	28

GENERAL CIRCULATION OF THE ATMOSPHERE	33
Overview	33
<i>J M Wallace, D W J Thompson, and P Beresford</i>	
Angular Momentum of the Atmosphere	43
<i>D A Salstein</i>	
Energy Cycle	51
<i>R Grotjahn</i>	
Weather Regimes and Multiple Equilibria	65
<i>F Molteni</i>	
Mean Characteristics	73
<i>R Grotjahn</i>	
Teleconnections	90
<i>S Nigam and S Baxter</i>	
 GLOBAL CHANGE	 110
Climate Record: Surface Temperature Trends	110
<i>P D Jones</i>	
Sea Level Change	121
<i>R S Nerem</i>	
Upper Atmospheric Change	128
<i>R G Roble</i>	
Biospheric Impacts and Feedbacks	132
<i>B A Hungate and G W Koch</i>	
 GRAVITY WAVES	 141
Overview	141
<i>D C Fritts</i>	
Buoyancy and Buoyancy Waves: Optical Observations	153
<i>M J Taylor and W R Pendleton, Jr</i>	
Buoyancy and Buoyancy Waves: Theory	160
<i>T J Dunkerton</i>	
Gravity Waves Excited by Jets and Fronts	164
<i>R Plougonven and F Zhang</i>	
Convectively Generated Gravity Waves	171
<i>T P Lane</i>	
 HYDROLOGY, FLOODS AND DROUGHTS	 180
Overview	180
<i>R C Bales</i>	
Deserts and Desertification	185
<i>V P Tchakerian</i>	
Drought	193
<i>S Quiring</i>	

Flooding	201
<i>C A Doswell III</i>	
Groundwater and Surface Water	209
<i>S Ge and S M Gorelick</i>	
Modeling and Prediction	217
<i>Z Yu</i>	
Palmer Drought Severity Index	224
<i>L Nkemdirim</i>	
Soil Moisture	232
<i>A Robock</i>	
LAND-ATMOSPHERE INTERACTIONS	240
Overview	240
<i>R E Dickinson</i>	
Canopy Processes	244
<i>P D Blanken</i>	
Trace Gas Exchange	256
<i>J N Cape and D Fowler</i>	
LIDAR	262
Atmospheric Sounding Introduction	262
<i>P S Argall and R Sica</i>	
Backscatter	270
<i>C M R Platt and R L Collins</i>	
Differential Absorption Lidar	277
<i>S Ismail and E V Browell</i>	
Doppler	289
<i>R M Hardesty</i>	
Raman	296
<i>D N Whiteman</i>	
Resonance	305
<i>C S Gardner and R L Collins</i>	
Magnetosphere	309
<i>G K Parks</i>	
MESOSCALE METEOROLOGY	316
Overview	316
<i>D J Parker</i>	
Cloud and Precipitation Bands	323
<i>R M Rauber and M Ramamurthy</i>	
Gust Fronts	331
<i>R Rotunno</i>	

Hail and Hailstorms	334
<i>C Knight, N Knight, and H E Brooks</i>	
Mesoscale Convective Systems	339
<i>A Laing</i>	
Microbursts	335
<i>R M Wakimoto</i>	
Severe Storms	361
<i>C A Doswell III</i>	
Waterspouts	369
<i>J H Golden</i>	
Bow Echoes and Derecho	384
<i>M L Weisman</i>	
Density Currents	395
<i>P G Baines</i>	
Convective Storms: Overview	401
<i>M L Weisman</i>	
MESOSPHERE	411
Atomic Species in the Mesopause Region	411
<i>M G Mlynczak and L A Hunt</i>	
Ionosphere	422
<i>M C Kelley</i>	
Metal Layers	430
<i>J M C Plane</i>	
Polar Summer Mesopause	436
<i>R H Varney and M C Kelley</i>	
VOLUME 4	
MIDDLE ATMOSPHERE	1
Planetary Waves	1
<i>A K Smith and J Perlwitz</i>	
Polar Vortex	12
<i>M R Schoeberl and P A Newman</i>	
Quasi-Biennial Oscillation	18
<i>T J Dunkerton, J A Anstey, and L J Gray</i>	
Semiannual Oscillation	26
<i>K Hamilton</i>	
Stratospheric Sudden Warmings	30
<i>A O'Neill, A J Charlton-Perez, and L M Polvani</i>	
Transport Circulation	41
<i>S E Strahan</i>	

Zonal Mean Climatology <i>P Braesicke</i>	50
MOUNTAIN METEOROLOGY	57
Overview <i>R B Smith</i>	57
Cold Air Damming <i>B A Colle</i>	62
Downslope Winds <i>D R Durran</i>	69
Katabatic Winds <i>T R Parish</i>	75
Land and Sea Breezes <i>R A Pielke, Sr</i>	80
Lee Vortices <i>C C Epifanio</i>	84
Lee Waves and Mountain Waves <i>D R Durran</i>	95
Orographic Effects: Lee Cyclogenesis <i>C Schär</i>	103
Valley Winds <i>D Zardi</i>	114
NUMERICAL MODELS	135
Chemistry Models <i>M P Chipperfield and S R Arnold</i>	135
Coupled Ocean-Atmosphere Models: Physical Processes <i>M Zhang</i>	144
General Circulation Models <i>C R Mechoso and A Arakawa</i>	153
Methods <i>J Thuburn</i>	161
Model Physics Parameterization <i>D J Stensrud, M C Coniglio, K H Knopfmeier, and A J Clark</i>	167
Parameter Estimation <i>A Aksoy</i>	181
Parameterization of Physical Processes: Clouds <i>R Forbes, C Jakob, and M Miller</i>	187
Parameterization of Physical Processes: Gravity Wave Fluxes <i>M J Alexander</i>	194
Parameterization of Physical Processes: Turbulence and Mixing <i>A Beljaars</i>	200

Spectral Models <i>F Baer</i>	212
Mesoscale Atmospheric Modeling <i>R A Pielke, Sr</i>	219
Cloud-System Resolving Modeling and Aerosols <i>W-K Tao and T Matsui</i>	222
Large-Eddy Simulation <i>C-H Moeng and P P Sullivan</i>	232
Regional Prediction Models <i>B W Golding</i>	241
Convective Storm Modeling <i>M D Parker</i>	246
OBSERVATIONS PLATFORMS	255
Balloons <i>J-P Pommereau</i>	255
Buoys <i>J M Hemsley</i>	264
Kites <i>B B Balsley</i>	268
Radiosondes <i>W F Dabberdt and H Turtiainen</i>	273
Rockets <i>M F Larsen</i>	285
OCEANOGRAPHIC TOPICS	290
General Processes <i>N C Wells</i>	290
Surface/Wind Driven Circulation <i>R X Huang</i>	301
Thermohaline Circulation <i>R X Huang</i>	315
Water Types and Water Masses <i>W J Emery</i>	329
OPTICS, ATMOSPHERIC	338
Optical Remote Sensing Instruments <i>G G Shepherd</i>	338
Airglow Instrumentation <i>M Conde</i>	346

OZONE DEPLETION AND RELATED TOPICS	353
Long-Term Ozone Changes <i>N R P Harris</i>	353
Ozone as a UV Filter <i>J E Frederick</i>	359
Ozone Depletion Potentials <i>D J Wuebbles</i>	364
Photochemistry of Ozone <i>G K Moortgat and A R Ravishankara</i>	370
Stratospheric Ozone Recovery <i>D J Hofmann and R Müller</i>	380
Surface Ozone Effects on Vegetation <i>M Ashmore</i>	389
Surface Ozone (Human Health) <i>M Lippmann</i>	397
PALEOCLIMATOLOGY	404
Ice Cores <i>E J Steig</i>	404
Varves <i>R Gilbert</i>	411
RADAR	415
Cloud Radar <i>T Uttal</i>	415
Incoherent Scatter Radar <i>M P Sulzer</i>	422
Mesosphere—Stratosphere—Troposphere and Stratosphere—Troposphere Radars and Wind Profilers <i>G Vaughan and D Hooper</i>	429
Meteor Radar <i>N J Mitchell</i>	438
Polarimetric Doppler Weather Radar <i>R J Doviak and R D Palmer</i>	444
Precipitation Radar <i>S E Yuter</i>	455
Synthetic Aperture Radar (Land Surface Applications) <i>R K Vincent</i>	470
VOLUME 5	
RADIATION TRANSFER IN THE ATMOSPHERE	1
Radiation, Solar <i>Q Fu</i>	1

Absorption and Thermal Emission <i>R M Goody and X Huang</i>	5
Cloud-Radiative Processes <i>Q Fu</i>	13
Non-local Thermodynamic Equilibrium <i>M López-Puertas and B Funke</i>	16
Scattering <i>M Mishchenko, L Travis, and A Lacis</i>	27
Ultraviolet Radiation <i>K Stamnes</i>	37
Ultraviolet, Surface <i>R McKenzie and S Madronich</i>	45
SATELLITES AND SATELLITE REMOTE SENSING	51
Aerosol Measurements <i>R A Kahn</i>	51
Earth's Radiation Budget <i>N G Loeb and B A Wielicki</i>	67
GPS Meteorology <i>S S Leroy</i>	77
Measuring Ozone from Space — TOMS and SBUV <i>R D McPeters and R S Stolarski</i>	87
Orbits <i>S Q Kidder</i>	95
Precipitation <i>G Liu</i>	107
Remote Sensing: Cloud Properties <i>P Yang and B A Baum</i>	116
Research <i>M D King</i>	128
Surface Wind and Stress <i>W T Liu</i>	138
Temperature Soundings <i>A Dudhia</i>	145
Water Vapor <i>J E Harries</i>	157
SOLAR SYSTEM/SUN, ATMOSPHERES, EVOLUTION OF ATMOSPHERES	163
Evolution of Earth's Atmosphere <i>Y L Yung, M L Wong, and E J Gaidos</i>	163
Planetary Atmospheres: Mars <i>R M Haberle</i>	168

Planetary Atmospheres: Venus <i>P J Gierasch and Y L Yung</i>	178
Solar Terrestrial Interactions: Climate Impact <i>J D Haigh</i>	183
Solar Winds <i>S T Suess and B T Tsurutani</i>	189
Meteors <i>P Jenniskens</i>	195
STATISTICAL METHODS	201
Data Analysis: Empirical Orthogonal Functions and Singular Vectors <i>C S Bretherton</i>	201
Data Analysis: Time Series Analysis <i>G R North</i>	205
STRATOSPHERIC CHEMISTRY TOPICS	211
Overview <i>J A Pyle</i>	211
Halogens <i>D Toohey</i>	215
Halogen Sources, Anthropogenic <i>A McCulloch and P M Midgley</i>	221
Halogen Sources, Natural (Methyl Bromide and Related Gases) <i>S Yvon-Lewis and J H Butler</i>	228
HO _x <i>T F Hanisco</i>	233
Hydrogen Budget <i>J E Harries</i>	238
Reactive Nitrogen (NO _x and NO _y) <i>Y Kondo</i>	242
Stratospheric Water Vapor <i>K H Rosenlof</i>	250
STRATOSPHERE/TROPOSPHERE EXCHANGE AND STRUCTURE	257
Global Aspects <i>J R Holton</i>	257
Local Processes <i>J F Lamarque and P Hess</i>	262
Tropopause <i>M Dameris</i>	269

SYNOPTIC METEOROLOGY	273
Anticyclones <i>S J Colucci</i>	273
Forecasting <i>D Mansfield</i>	280
Weather Maps <i>R Reynolds</i>	289
Cyclogenesis <i>G J Hakim</i>	299
Extratropical Cyclones <i>A Joly</i>	304
Fronts <i>D M (David) Schultz and W Blumen</i>	337
Fronts in the Lower Stratosphere <i>A L Lang</i>	344
Frontogenesis <i>D M (David) Schultz</i>	353
Jet Streaks <i>P Cunningham and D Keyser</i>	359
Lake-Effect Storms <i>P J Sousounis</i>	370
Polar Lows <i>I A Renfrew</i>	379
Thermal Low <i>R H Johnson</i>	386
 THERMODYNAMICS	 391
Humidity Variables <i>J A Curry</i>	391
Moist (Unsaturated) Air <i>J A Curry</i>	394
Saturated Adiabatic Processes <i>J A Curry</i>	398
 Thermosphere <i>S C Solomon and R G Roble</i>	 402
 VOLUME 6	
TROPICAL CYCLONES AND HURRICANES	1
Overview and Theory <i>R A Tomas and P J Webster</i>	1

Hurricane Dynamics <i>Y Wang</i>	8
Hurricane Predictability <i>J A Sippel</i>	30
Hurricanes: Observation <i>F D Marks</i>	35
Tropical Cyclogenesis <i>Z Wang</i>	57
Tropical Cyclones and Climate Change <i>T R Knutson</i>	65
Tropical Cyclones in the Western North Pacific <i>J C L Chan</i>	77
Tropical Cyclones: Secondary Eyewall Formation <i>C-C Wu and Y-H Huang</i>	85
TROPICAL METEOROLOGY AND CLIMATE	91
El Niño and the Southern Oscillation: Observation <i>N Nicholls</i>	91
El Niño and the Southern Oscillation: Theory <i>P Chang and S E Zebiak</i>	97
Equatorial Waves <i>M C Wheeler and H Nguyen</i>	102
Hadley Circulation <i>J Lu and G A Vecchi</i>	113
Intertropical Convergence Zone <i>D E Waliser and X Jiang</i>	121
Intraseasonal Oscillation (Madden–Julian Oscillation) <i>R A Madden</i>	132
Madden–Julian Oscillation: Skeleton and Conceptual Models <i>A J Majda and S N Stechmann</i>	137
Monsoon: Overview <i>J Slingo</i>	146
Monsoon: Dynamical Theory <i>P J Webster and J Fasullo</i>	151
Monsoon: ENSO–Monsoon Interactions <i>K-M Lau</i>	165
Tropical Climates <i>S Hastenrath</i>	170
Walker Circulation <i>K-M Lau and S Yang</i>	177

TROPOSPHERIC CHEMISTRY AND COMPOSITION	182
Aerosols/Particles <i>J H Seinfeld</i>	182
Aliphatic Hydrocarbons <i>J Rudolph and O Stein</i>	188
Aromatic Hydrocarbons <i>I Barnes</i>	204
Biogenic Hydrocarbons <i>A Guenther</i>	214

LIST OF CONTRIBUTORS

A. Aksoy
University of Miami, Miami, FL, USA; and NOAA Hurricane Research Division, Miami, FL, USA

M.J. Alexander
NorthWest Research Associates (NWRA), Boulder, CO, USA

W.M. Angevine
CIRES, University of Colorado; and NOAA Earth System Research Laboratory, Boulder, CO, USA

J.A. Anstey
University of Oxford, Oxford, UK

K.L. Aplin
University of Oxford, Oxford, UK

A. Arakawa
University of California, Los Angeles, CA, USA

P.S. Argall
The University of Western Ontario, London, ON, Canada

S.R. Arnold
University of Leeds, Leeds, UK

M. Ashmore
University of York, York, UK

F. Baer
University of Maryland, College Park, MD, USA

P.G. Baines
University of Melbourne, Melbourne, VIC, Australia

A.R. Baker
University of East Anglia, Norwich, UK

M.B. Baker
University of Washington, Seattle, WA, USA

R.C. Bales
University of Arizona, Tucson, AZ, USA

B.B. Balsley
University of Colorado, Boulder, CO, USA

G.A. Ban-Weiss
Lawrence Berkeley National Laboratory, Berkeley, CA, USA; and University of Southern California, Los Angeles, CA, USA

I. Barnes
University of Wuppertal, Wuppertal, Germany

P. Bartello
McGill University, Montréal, QC, Canada

B.A. Baum
University of Wisconsin–Madison, Madison, WI, USA

D. Baumgardner
Universidad Nacional Autónoma de México, Mexico City, D.F., Mexico

S. Baxter
University of Maryland, College Park, MD, USA

A.J. Bedard, Jr.
National Oceanic and Atmospheric Administration, Boulder, CO, USA

A. Beljaars
European Centre for Medium-Range Weather Forecasts, Reading, England

N. Bellouin
University of Reading, Reading, UK

A. Benilov
Acute Solutions, Highlands, NJ, USA

P. Beresford
European Centre for Medium-Range Weather Forecasts, Reading, UK

A. Betts
Atmospheric Research, Pittsford, VT, USA

M.P. Bishop
Texas A&M University, College Station, TX, USA

P.D. Blanken

PREFACE TO THE FIRST EDITION

A half century ago the American Meteorological Society published the *Compendium of Meteorology*, which in a single volume of 1334 pages summarized the state of understanding of the atmosphere at that time. A perusal of the contents of that volume indicates that although a broad range of topics was covered, the vast bulk of the volume was devoted to traditional meteorological topics such as atmospheric dynamics, cloud physics, and weather forecasting. Barely 4 percent of the volume was devoted to articles related to atmospheric chemistry or air pollution and, of course, none of the volume was devoted to techniques such as satellites and remote sensing.

As Sir John Mason aptly notes in his foreword to the present work, the atmospheric sciences have expanded in scope enormously over the past 50 years. Topics such as atmospheric chemistry and global climate change, of only marginal interest 50 years ago, are now central disciplines within the atmospheric sciences. Increasingly, developing areas within the atmospheric sciences require students, teachers, and researchers to familiarize themselves with areas far outside their own specialties. This work is intended to satisfy the need for a convenient and accessible references source covering all aspects of atmospheric sciences. It is written at a level that allows undergraduate science and engineering students to understand the material, while providing active researchers with the latest information in the field.

More than 400 scientists, from academia, government, and industry have contributed to the 330 articles in this work. We are very grateful to these authors for their success in providing concise and authoritative summaries of complex subjects. As editors, we have benefited from the chance to learn from these articles, and we believe that all students and active scientists who want to increase their knowledge of the atmosphere will benefit enormously from access to this work.

We are also grateful to the 31 members of the Editorial Advisory Board who have guided us in our coverage of the very broad range of topics represented in this encyclopedia. Their willingness to suggest topics and authors, and to carefully review draft articles has contributed significantly to our success.

The production of this multivolume encyclopedia would not have been possible without the dedicated work of the staff of the Major Reference Works group at Academic Press. We are especially grateful to the Major Reference Work Development Manager, Colin McNeil, who has worked closely with us during the entire process. Finally, we appreciate the liberal use of color figures in the printed encyclopedia.

PREFACE TO THE SECOND EDITION

Since the publication of the first edition of the *Encyclopedia of Atmospheric Sciences*, significant advances in research have been achieved all across the broad and expanding spectrum of the field and related disciplines. In particular, climate science with primary input from the atmospheric research emerges as a new field and integrator of interlocking peripheral disciplines over the last decade. These events have demanded the solicitation of new and updated articles for the 2003 edition. Some articles from the earlier publication were judged to be of such a fundamental and enduring nature that they did not require modification. But huge amounts of new information from Earth-orbiting satellite observatories have brought much new insight to the field. In addition there are new findings in many areas such as the latest simulations of meteorological and climatic processes of interest as well as simulations and observations of the composition and interaction of the field's chemical constituents. While interest in the ozone hole and its ramifications may have reached a plateau, ever more understanding of the stratosphere and its role in climate change emerges. The study of past climates provides new means of testing climate models and theories. In weather prediction we see new progress on how data are to be better assimilated for much improved initialization of the forecast model leading to the promise of more accurate predictions of severe weather and tropical cyclones over longer lead times. These are just a few of the new features of the second edition.

The editors of the second edition are greatly indebted to our predecessors in the first edition. They set the outline of topics and solicited the original authors, while establishing a high standard for the content of this publication. In many cases we decided to reprint those articles or request only minor updates. Nevertheless, many articles in this edition are entirely original, based on which we also made significant reorganization of the content. We are proud of our product and hope it provides the same assistance to students, researchers, and practitioners throughout the science and engineering communities.

EDITOR BIOGRAPHIES

Gerald R North received his PhD in theoretical physics from the University of Wisconsin in 1966. After postdoctoral research at the University of Pennsylvania he became a faculty member in physics at the University of Missouri–St. Louis. He shifted his research focus to climate science research during his sabbatical year at the National Center for Atmospheric Research, where he won the Outstanding Paper Award in 1975. He moved to NASA Goddard Space Flight Center (GSFC) in 1978 where he was awarded the NASA Medal for Research Excellence. During his stay at GSFC, he was the proposer and first study scientist for the Tropical Rainfall Measuring Mission, which was launched in 1997 and is still orbiting in 2014.

He moved to Texas A&M University in 1986 as a university distinguished professor of atmospheric sciences where he served as department head from 1995 to 2003. He has served as editor-in-chief of the *Reviews of Geophysics* and is recognized as one of the most cited authors in geosciences (Web of Science). He has chaired and/or served on a number of national committees and is a Fellow of the American Geophysical Union, American Meteorological Society (AMS) and the American Association for the Advancement of Science, and winner of the Jule Charney Award for Research (AMS).

He has published about 150 refereed papers not including many book chapters and reviews. His books include *Paleoclimatology*, co-authored with Thomas Crowley, and *An Introduction to Atmospheric Thermodynamics* co-authored with Tatiana Erikhimova.

North's interests are focused on the use of mathematical and statistical tools to solve climate problems over a wide range of issues including: analytical solutions of simplified energy balance climate models, use of random field techniques in representing and interpreting climate data and model simulations, detection of deterministic signals in climate change, statistical analysis satellite remote sensing for mission planning and analysis of data, paleoclimate problems using simplified climate models.

John Pyle obtained a BSc in Physics at Durham University before moving to Oxford where he completed a DPhil in Atmospheric Physics, helping to develop a numerical model for stratospheric ozone studies. After a short period at the Rutherford Appleton Laboratory he moved to a lectureship at Cambridge University in 1985. In 2000 he was appointed professor of atmospheric science and since 2007 has been the 1920 professor of physical chemistry. He is a Professorial Fellow at St Catharine's College. He has been a codirector of Natural Environment Research Council's National Centre for Atmospheric Science, where he is currently Chief Scientist.

His research focuses on the numerical modelling of atmospheric chemistry. Problems involving the interaction between chemistry and climate have been addressed; these range from stratospheric ozone depletion to the changing tropospheric oxidizing capacity and have included the environmental impact of aviation, land use change, biofuel technologies, and the hydrogen economy. He has studied palaeochemistry problems as well as the projected atmospheric composition changes during the current century. He has published more than 250 peer reviewed papers.

He played a major role in building an EU stratospheric research programme in the 1990s, coordinating several major field campaigns. He has contributed to all the WMO/UNEP assessments on stratospheric ozone since the early 1980s and is now one of the four international cochairns on

the Scientific Assessment Panel, responsible for these assessments. He was a convening lead author in the IPCC Special report "Safeguarding the ozone layer and the global climate system," published in 2006.

He was elected Fellow of the Royal Society in 2004 and an American Geophysical Union Fellow in 2011. He was awarded the Cambridge ScD degree in 2012. Other honours and awards include membership of Academia Europaea (1993), Royal Society of Chemistry (Interdisciplinary award, 1991, and John Jeyes lectureship, 2008), and the Royal Meteorological Society Adrian Gill Prize, in 2004.

Fuqing Zhang is a professor with tenure in the Department of Meteorology at the Pennsylvania State University, with a joint appointment in the Department of Statistics, along with an endowed position as the E Willard & Ruby S Miller Faculty Fellow at the College of Earth and Mineral Sciences at the Pennsylvania State University. His research interests include atmospheric dynamics and predictability, data assimilation, ensemble forecasting, tropical cyclones, gravity waves, mountain plains and sea-breeze circulations, warm-season convection, and regional-scale climate. He earned his BS and MS in meteorology from Nanjing University, China in 1991 and 1994, respectively, and his PhD in atmospheric science in 2000 from North Carolina State University.

He spent seven years as an assistant and then associate professor at Texas A&M University before coming to Penn State University as a full professor in 2008. In 2000, he spent a year and a half as a postdoctoral fellow at the National Center for Atmospheric Research. He also held various visiting scholarship appointments at various academic and research institutions including the National

Center for Atmospheric Research in Boulder, Colorado; the Navy Research Laboratory in Monterey, California; NOAA/AOML Hurricane Research Division, Miami, Florida; Peking University and Nanjing University, China; the Chinese State Key Laboratory of Severe Weather in Beijing, China; and Laboratoire de Meteorologie Dynamique, École Normale Supérieure in Paris, France.

He has authored/co-authored about 130 peer reviewed journal publications and has given more than 160 keynote speeches or invited talks at various institutions and meetings. He has served as principal investigator/co-principal investigator for 30 federal or state-sponsored research grants. He has chaired/cochaired more than 10 scientific meetings or workshops. He also served on various review or advisory panels for numerous organizations that include National Science Foundation, Office of Naval Research, NASA, NOAA, and National Academies. He has also served as editor of several professional journals including *Monthly Weather Review*, *Science China*, *Atmospheric Science Letter*, *Acta Meteorologica Sinica*, and *Computing in Science & Engineering*.

He has also received numerous awards for his research and service. Notably, in 2007 he received the **Outstanding Publication Award** from the National Center for Atmospheric Research. In 2009, was the sole recipient of the American Meteorological Society's 2009 **Clarence Leroy Meisinger Award** "for outstanding contributions to mesoscale dynamics, predictability, and ensemble data assimilation." Most recently, he received the 2014 American Meteorological Society's **Banner Miller Award** "for valuable insights into incorporating real-time airborne Doppler radar measurements via ensemble data assimilation, leading to improvements in forecasts of tropical cyclone track and intensity."

GUIDE TO USING THE ENCYCLOPEDIA

Structure of the Encyclopedia

The material in the encyclopedia is not arranged by ordinary alphabetical order, but by alphabetical order according to 49 principal topic areas taken to allow all papers belonging to each principal topic to appear together in the same volume. Within each principal subject, article headings are also arranged alphabetically, except where logic dictates otherwise. For example, overview articles appear at the beginning of a section.

There are four features that help you find the topic in which you are interested:

- i. the contents list
- ii. cross-references to other relevant articles within each article
- iii. a full subject index
- iv. contributors

i. Contents List

The contents list, which appears at the front of each volume, lists the entries in the order that they appear in the encyclopedia. It includes both the volume number and the page number of each entry.

ii. Cross-references

All of the entries in the encyclopedia have been cross-referenced. The cross-references, which appear at the end of an article as a See also list, serve four different functions:

- i. To draw the reader's attention to related material in other entries

- ii. To indicate material that broadens and extends the scope of the article
- iii. To indicate material that covers a topic in more depth
- iv. To direct readers to other articles by the same author(s)

Example

The following list of cross-references appears at the end of the article.

See also: **Biogeochemical Cycles:** Biogeochemistry of Iodine. **Stratospheric Chemistry Topics:** HO_x; Halogen Sources, Natural (Methyl Bromide and Related Gases); Halogens; Hydrogen Budget; Overview; Reactive Nitrogen (NO_x and NO_y).

iii. Index

The index includes page numbers for quick reference to the information you are looking for. The index entries differentiate between references to a whole article, a part of an article, and a table or figure.

iv. Contributors

At the start of each volume there is list of the authors who contributed to that volume.

Synopsis

Climate is defined and the variations of average or expected temperature and precipitation on the Earth as a function of location and season are briefly described. The role of the energy balance and greenhouse effect of the Earth, the distribution of insolation, and the role of oceans and topography in determining climate are explained. Past climate changes are introduced, including much warmer climates millions of years ago and the succession of ice ages in the past several millions of years. The primary determinant of the future climate will likely be the modification of atmospheric composition by human activities.

Introduction

Climate is the composite or generalization of weather conditions of a region as a function of season. It can be expressed in terms of the expected values of meteorological variables such as temperature, precipitation, pressure, humidity, cloudiness, sunshine, and winds. The expected values are usually obtained by averaging observations over a number of years. A complete description of the climate would also include information on the year-to-year variability. Climatology is the scientific study of climate. A complete understanding of climate requires a thorough understanding of the atmosphere and its physical and chemical interactions with the ocean and the land surface.

Life in the ocean and on the land influences the composition of the air, the color of the ocean, and the exchange of energy and moisture between the land surface and the atmosphere.

Climate is important for humanity and life on the Earth, since it has set the context for human evolution and subsequent social, political, and historical developments. In the modern world, it influences agriculture, water resources, human health, and energy use. It continues to play an important role in natural ecology and the interaction of human endeavor with Earth's biological and geochemical resources. Because of the large human population of the Earth and the adoption of technology by societies, humans now have the ability to make relatively rapid changes in Earth's global climate.

Description of Climate

The average surface temperature of the Earth is about 288 K or 15 °C. The global average precipitation is about 1 m year⁻¹. The climate of a given location varies with latitude, altitude, and geographical conditions (Figure 1). Seasonal variations are greater in higher latitudes and in continental rather than maritime areas (Figure 2). Oceans have a large capacity to store heat, so that seasonal variations in surface temperature are tempered by heat exchange with the ocean.

The distribution of precipitation is more complex. Precipitation is greatest near the equator, reduced in subtropical latitudes (15°–30°), and increases again in middle latitudes (Figure 3). The rainfall maximum near the equator is associated with the general convergence of wind at low levels and the

high water vapor content of tropical air. This precipitation maximum moves north and south across the equator following the position of the Sun relative to the equator. The very low precipitation values that occur in the tropics are associated with downward motion and divergence of the surface winds. Precipitation maxima occur in midlatitudes where cyclonic storms are frequent and produce heavy rainfall. Two relatively strong precipitation maxima in the Northern Hemisphere are associated with the storm tracks over the western Pacific and Atlantic Oceans.

Annual variations of temperature and precipitation vary greatly with location. In the tropics, temperature variations are usually modest, but precipitation can vary from complete drought in some seasons to torrential rains in another. Land areas that are downwind of large water masses generally have

Figure 1 Global surface temperature maps January and July and January minus July. Contour interval is 4 K. Data are 2 m temperatures from the analysis products of The European Centre for Medium-Range Weather Forecasts for the period 1985–94.

Figure 2 July minus January difference in surface air temperature. Contour interval is 5 K.

smaller seasonal temperature variations than locations in the center of large continents. Good examples of maritime and continental climates are Seattle and Minneapolis (**Figure 4**). Minneapolis has a much larger seasonal variation of temperature. The variations of precipitation in these two regions are also very different. Seattle has a wintertime precipitation maximum associated with the midlatitude storm activity. Minneapolis has a summertime rainfall maximum that comes largely from thunderstorms. The annual temperature variation of New York City is influenced by the large continental upwind to the west and so is quite large. New York gets both wintertime storm precipitation and summertime convective precipitation, so that monthly precipitation is more nearly evenly spread over the year. The annual total precipitation in New York City (120 cm) is greater than that of Seattle (95 cm).

Global Energy Balance

The mean temperature at the surface of the Earth is determined by the flow of energy through the climate system, which consists of the atmosphere, ocean, and land surface. The source of energy for the planet is radiation emitted by the Sun. Although Earth has an internal energy source from radioactive decay, this source is too small to influence the global mean surface temperature. At the average position of the Earth in its orbit about the Sun, the Sun provides about 1360 W m^{-2} of total solar irradiance. The solar irradiance varies as the inverse square of the distance from the Sun. Because the Earth is approximately spherical in shape, the ratio of its shadow area to its surface area is 4. So to get the solar energy available per unit of surface area, the total solar irradiance must be divided by 4, yielding about 340 W m^{-2} or the energy equivalent of about 3.4 100-W light bulbs for each square meter of the Earth. Averaged over the whole Earth, about 70% of this flux is absorbed by the Earth and about 30% is reflected back to space without heating the Earth. The fraction that is reflected is called

the albedo, from a Greek word meaning whiteness. The energy that is absorbed is converted into heat and later emitted back to space as thermal infrared radiation.

The simplest model for the global mean temperature T of the Earth equates the absorbed solar radiation with the emitted terrestrial radiation, assuming that the Earth emits like a blackbody.

$$\frac{S}{4}(1 - \alpha) = \sigma T^4 \quad [1]$$

where S is the total solar irradiance, α is the albedo, and $\sigma = 5.67 \times 10^{-8} \text{ W m}^{-2} \text{ K}^{-4}$ is the Stefan-Boltzmann blackbody emission constant. If this equation is solved for the blackbody emission temperature of the Earth, a value of about 255 K, or -18°C , is obtained which is much less than the global mean surface temperature of 288 K, or 15°C . The emission temperature of the Earth is equal to the average temperature of the atmosphere about 5 km above the surface, and indeed, most of the energy that the Earth emits to space is emitted from the atmosphere rather than the surface.

A diagram showing the energy flow through the global climate system is given in **Figure 5**. Although nearly half of the solar energy that enters the climate system is absorbed at the surface, very little of the infrared radiation emitted from Earth's surface escapes directly to space. The atmosphere absorbs most of the infrared radiation emitted from the surface, primarily by water vapor, clouds, and carbon dioxide gas. Moreover, the atmosphere emits infrared radiation downward toward the surface, and the energy supplied to the surface by this downward infrared flux is nearly twice as great as the amount of energy supplied to the surface from the Sun. The transparency of the atmosphere to solar radiation combined with the opaqueness of the atmosphere to infrared radiation result in a heating effect that raises the surface temperature above the value that it would have in the absence of the atmosphere. This is often called the atmospheric

Figure 3 Global precipitation maps for January and July. Contour interval 2 cm month^{-1} . Data are from the Global Precipitation Climatology Project.

greenhouse effect. The greenhouse effect also reduces the amplitude of the diurnal cycle in surface temperature, the daily variation of temperature associated with the rising and setting of the Sun. Because the downward longwave emission from the atmosphere continues after the Sun sets, the fall of temperature after sunset is much less than it would be in the absence of the atmosphere. At high altitudes, the daily variation of temperature is greater because the mass of atmosphere above the surface is less and the greenhouse effect is therefore reduced. Because water vapor is the principle greenhouse gas, the strength of the greenhouse effect increases with temperature and relative humidity.

A net radiative input heats the surface of the Earth, and the net effect of radiation on the atmosphere is to cool it at the rate of about $1.5^\circ\text{C day}^{-1}$. Heat is transferred from the surface to the atmosphere by atmospheric motions that carry heat and moisture upward. The release of latent heat of vaporization

stored in water vapor during condensation is the largest heating term in the atmosphere and offsets atmospheric cooling by radiation emission. The global mean precipitation rate of 1 m year^{-1} corresponds to an atmospheric heat input of 80 W m^{-2} .

Continuous heating of the surface and cooling of the atmosphere by radiative processes drive convective instability and the hydrologic cycle within the Earth's climate system. Evaporation is greater than precipitation over the world's oceans. The excess water is transported to the land areas where the average precipitation exceeds the evaporation. The excess of precipitation over evaporation in land areas returns to the oceans as runoff in rivers (Figure 6). The supply of water from the ocean supports life on the land, and the return of minerals and other elements of life to the ocean in rivers supports life in the ocean. The hydrologic cycle is also a key element of the chemical and biological cycling of carbon through the Earth

Figure 4 Annual cycles of climatological monthly temperature (solid line) and precipitation (dashed line) at four cities.

system that regulates atmospheric carbon dioxide on timescales of millennia and longer.

Seasonal and Latitudinal Insolation Variations

The seasonal and latitudinal distribution of insolation is an important determinant of climate. The instantaneous insolation per unit of surface area is given by the total solar irradiance times the cosine of the solar zenith angle, the angle between local vertical and the Sun. The daily average insolation available at the top of the atmosphere is given as a function of latitude and season in [Figure 7](#). The insolation decreases with increasing latitude, except in summer, and the annual variation of insolation is greatest near the poles, where 6 months of darkness alternate with 6 months of daylight. In polar regions during summer, the available insolation is greater than that at the equator, because, although the Sun is near the horizon, it shines 24 h a day at the poles during the summer half-year. The insolation available during Southern Hemisphere summer is about 7% greater than that available during Northern Hemisphere summer, because Earth's orbit is not perfectly circular and at the present time, the Earth is closer to the Sun during Southern Hemisphere summer.

On timescales of millennia, the distribution of insolation with latitude and season changes as the parameters of Earth's orbit vary in response to dynamical interactions with the orbits of other planets. The tilt of the axis of rotation with respect to the plane of Earth's orbit varies with a period of

41 000 years. In the last few million years the tilt angle, or obliquity, has varied between 22° and 24.5° . It is currently 23.45° . The eccentricity or degree to which Earth's orbit differs from a perfect circle varies with periods of 100 000 and 400 000 years. The season when the Earth makes its closest approach to the Sun, the perihelion of the orbit, varies with periods near 20 000 years.

Transport of Energy and the Circulation of the Atmosphere and Ocean

Much more solar energy is available to heat tropical latitudes than high latitudes. In the annual average, net radiative energy is input into tropical latitudes and high latitudes lose energy ([Figure 8](#)). The heating of the tropics and cooling of the polar regions drive circulations in the atmosphere and ocean that transport heat from tropical to polar regions. The ocean and the atmosphere have similarly important roles in poleward transport, with the ocean transport larger in subtropical latitudes (20° N and 20° S) and the atmosphere dominating at middle and high latitudes (50° N and 50° S). Transport in the atmosphere comprises latent, thermal, and potential energy transports. In tropical latitudes, upward motion near the equator and downward motion in subtropical latitudes are prominent features of the atmospheric circulation. At low levels, this requires equatorward winds that are turned westward by Earth's rotation to form the trade winds. At upper levels, the poleward flow is turned eastward by Earth's rotation

Figure 5 Energy flow through the global climate system.

Figure 6 Global cycling of water between ocean and land. Reproduced from Hartmann, D.L., 1994, *Global Physical Climatology*, Academic Press, San Diego, CA.

to form the subtropical jet stream, which is a band of high winds around 30° N and 30° S at around 12 km altitude. The general rising near the equator and sinking in the subtropical latitudes of the winter hemisphere is called the Hadley circulation, after a seventeenth century meteorologist. The Hadley circulation extends only to about 30° of latitude. Beyond that the circulation becomes unstable and breaks down into eddies. These eddies are very efficient at transporting energy poleward, and in middle latitudes, the poleward transport of heat is accomplished mostly by atmospheric eddies or storms. The structure of these storms is such that warm, humid parcels of air move poleward and cold, dry parcels of air move toward

the equator. Storms thus result in a net transport of heat and moisture toward the poles. Because warm, humid parcels within these storms are pushed upward as they are pushed poleward, midlatitude storms also produce heavy precipitation.

Poleward movement of warm water parcels and equatorward movement of cold water parcels produce poleward heat transport in the ocean. The most visible examples of this are the warm western boundary currents of the Atlantic and Pacific oceans – the Gulf Stream and the Kuroshio Current. These are narrow streams of warm water that flow poleward at the western margins of the oceans. The Gulf Stream can carry warm, salty water all the way from the tropics to the vicinity of Northern Norway. These currents account for the relative warmth of the oceans in middle latitudes and have a significant influence on the climate. Because of the shape and far northward extent of the Atlantic Ocean, the Gulf Stream and the associated deep overturning circulation of the Atlantic Ocean have a dramatic effect on the climate and its variability that has a global reach.

The western boundary currents are generally shallow surface currents. In the North Atlantic Ocean, warm, salty water travels very far north, where it is cooled without substantial dilution of the salt content. Because the density of seawater depends mostly on salinity near the freezing point, the cooled Gulf Stream water becomes some of the densest water in the ocean

Figure 7 Daily insolation at the top of the atmosphere as a function of season and latitude. Reproduced from Hartmann, D.L., 1994, *Global Physical Climatology*, Academic Press, San Diego, CA.

Figure 8 Annually averaged absorbed solar radiation emitted longwave radiation and net radiation at the top of the atmosphere as functions of latitude. Data are from the Earth Radiation Budget Experiment.

and sinks to near the bottom. It then returns equatorward and may travel as far as the North Pacific before it rises to the surface again. The density-driven circulation of the deep ocean is called the thermohaline circulation. The formation of deepwater in the North Atlantic Ocean creates a convergence of surface water, which allows more warm water to flow in from the south and heat the high latitude regions near the North Atlantic. Deep water is not formed in the North Pacific because the Pacific is not as salty as the Atlantic. The salinity of the oceans differs because the atmospheric circulation carries freshwater from the Atlantic basin to the Pacific. Major variations in the intensity of the thermohaline circulation in the North Atlantic are known to have occurred during ice ages. Evidence from Greenland ice cores suggests that the formation of deepwater has switched on and off on timescales of centuries or less during glacial periods.

Topographic Effects

Air pressure and density decrease rapidly with altitude. The air pressure at 5 km above sea level is only half of that at the surface. The air temperature at 5 km above the surface of the ocean is about 30°C colder than the ocean surface. When the land extends higher into the atmosphere, the surface pressure and temperature both decrease. If the land is heated by the Sun, it will be warmer than the air at the same pressure that is not in contact with the land. This results in the generation of buoyancy of the air in contact with the land, which may cause it to rise. A dramatic example of this is the seasonal variation in winds and precipitation over southern Asia. When the Sun heats the Himalayas during Northern Hemisphere summer, air at low levels is drawn toward the Himalayas, resulting in heavy precipitation in the mountains and the adjoining lowlands. During winter, the situation is reversed and air flows from the continent toward the ocean. During the Northern Hemisphere winter, precipitation near the Himalayas is reduced and precipitation over the equatorial Indian Ocean is increased. This seasonal reversal in winds and associated precipitation changes is called the Asian monsoon. A muted form of the same seasonal variation occurs over the tropical and subtropical Americas.

When air approaches a topographic obstruction and is forced to pass over it, much of the moisture in the air is condensed out on the windward side of the topography, and the leeward side can be quite arid if it is consistently blocked from maritime sources of water vapor. The Cascade and Sierra Nevada Mountains, for example, block the flow of moisture from the Pacific Ocean to the Great Basin between the coastal mountains and the Rocky Mountains farther inland. The Himalayas prevent moisture from the Indian Ocean from reaching central Asia.

Topographic barriers also divert the flow of air by generating waves in the atmosphere. During winter, the mountains of

western North America generate a stationary upstream high-pressure system and downstream low-pressure system. This is associated with equatorward flow on the lee of the Rocky Mountains, which makes the center of North America colder than it would be in the absence of topography.

Climate Variability and Change

It is known that the climate of the Earth has varied greatly in the past. During the Cretaceous period 65–135 million years ago, the climate was much warmer. Tropical plants and dinosaurs ranged far north above the Arctic Circle. On these long time-scales, continental drift has altered the arrangement of the continents, which influences the climate. It is likely that atmospheric greenhouse gases such as carbon dioxide or methane were much higher during the Cretaceous period. Changes in atmospheric greenhouse gas concentrations equivalent to a factor of 5 or 10 increase in carbon dioxide seem to be required to explain the similarity of tropical and polar surface temperatures during the Cretaceous and may have been made more likely by the distribution of continents and oceans at that time.

Twenty thousand years ago, much of North America and Europe were covered with sheets of ice several kilometers thick, and a similar glacial age occurred about 140 000 years ago. More recent variations in climate such as the succession of ice ages over the last several million years appear to be triggered by changes in Earth's orbital parameters. A large tilt of Earth's axis of rotation relative to the plane of Earth's orbit about the Sun favors an interglacial climate, because summertime and annual mean insolation in high latitudes increase with larger tilt. When Northern Hemisphere summer solstice occurs, the Earth is closest to the Sun; this also acts to reduce the ice piled on the northern continents and leads to interglacial climate conditions.

The effect of insolation variations is amplified by ice albedo feedback and biogeochemical feedbacks affecting the concentration of carbon dioxide and other greenhouse gases in the atmosphere. As the Earth cools, more of the surface of the Earth is covered with ice. Because ice has a higher albedo than other surfaces, this leads to less solar absorption by the planet and further cooling. The carbon cycle feedbacks are less well known, but changes in the ocean circulation and changes in the supply of trace metals to the ocean have been suggested as means of coupling decreased temperature to decreased carbon dioxide. On timescales of thousands of years, the atmospheric carbon dioxide concentration is tied closely to the carbon dioxide in the ocean. In the surface of the ocean, carbon dioxide is removed by photosynthetic life. Photosynthetic life in the ocean is limited by the amount of nutrients and trace metals that are present in the illuminated zone near the surface. Ice ages are known to be dustier than interglacial epochs like the current one. During ice ages, stronger winds mix the ocean more effectively and can bring more nutrients to the surface from depth. Stronger winds also loft more continental dust containing trace metals and carry it to regions of the ocean far removed from continents where trace metals required for photosynthesis would otherwise be lacking.

Climate also experiences significant year-to-year and decadal variations. These result from the natural internal variability of the climate. The El Niño Southern Oscillation (ENSO) phenomenon is a coupled ocean–atmosphere mode of variability with a timescale from 2 to 7 years, which is centered in the equatorial Pacific. During ENSO warm events, the equatorial SST in the east Pacific rises several degrees above normal and convection that is normally present in the far west Pacific may extend all the way to coastal South America. The rainfall that normally occurs in the western equatorial Pacific and Indonesia follows the warm water eastward into the central Pacific. The movement of the localized convective heating in the atmosphere drives atmospheric waves that may influence weather in middle latitudes. ENSO variability may be coupled to longer term variability in the North Pacific Ocean. Year-to-year variations in surface temperature may be caused by explosive volcanic eruptions that inject large amounts of sulfur-bearing gases into the stratosphere, where fine aerosol particles of sulfuric acid can reflect sunlight.

Decadal variations of climate have been observed, which seem to be related to interactions between atmosphere and ocean. Weather anomalies during winter in middle latitudes can drive thermal anomalies in the oceanic mixed layer and thermocline structure, which are then sealed under a shallow, warm oceanic mixed layer during the following summer. With the onset of surface cooling and turbulent mixing in the following winter, these thermal anomalies can be uncovered and influence the climate, thus giving climate anomalies a year-to-year persistence in middle latitudes. Ocean current circulations in middle latitudes can also transport these anomalies from place to place.

Human-Induced Climate Change

The concentrations of atmospheric greenhouse gases and aerosol particles in the atmosphere have been changing over time in response to human activities. From ice bubbles trapped in ice cores and other evidence, it was known that the concentration of carbon dioxide just prior to the industrial revolution was about 275 ppmv. The concentration has increased at a rate of about 0.5% per year so that the difference between the preindustrial value and the current value is larger than the differences between preindustrial and ice age conditions (Figure 9). Scientists are certain that recent changes in carbon dioxide concentration are caused by fossil fuel use by humans, because the isotopic composition of carbon derived from fossil fuels such as coal, oil, and natural gas is different from carbon that may have come from other sources.

Because carbon dioxide is an important greenhouse gas, its increase can lead to increases in global mean surface temperature. In addition to carbon dioxide, the concentrations of nitrous oxide, methane, and some industrially created greenhouse gases are also increasing in the atmosphere. The effects of these and projected future changes can be studied with global climate models. The known physics of the climate system can be incorporated into these computer models. Because of the wide range of spatial and temporal scales in the climate system, current limitations on computer power, and some gaps in the understanding of the climate system, these projections remain

Figure 9 Carbon dioxide for last 400 000 years. Data are from Vostok, Antarctica, and Siple Station, Greenland ice cores and modern instrumental data from Mauna Loa, Hawaii.

somewhat uncertain. Key feedback processes such as the cloud formation need to be treated with very approximate methods. Nonetheless, the basic physics of the greenhouse effect can be calculated precisely and scientists believe that human-induced changes in atmospheric composition have caused much of the recent warming of the surface temperature of the Earth. Many of the warmest years in the global temperature record have occurred in the last two decades, and the land has warmed faster than the ocean (**Figure 10**).

Changes in Earth's climate will occur in the future as a result of human activities. Because of the large heat capacity of the oceans, the warming resulting from greenhouse gases lags several decades behind the greenhouse gas changes. It is estimated that about another 0.5°C of warming should result from changes in the composition of the atmosphere that humans have already caused, and human modification of the atmosphere is continuing at an increasing rate.

Synopsis

Carbon dioxide plays a significant role in the Earth's life cycle and in controlling the global climate. It is a greenhouse gas that makes life on Earth possible, but mankind is currently in the process of altering the global carbon cycle through land use practices and burning of fossil fuels. This article looks at the history of atmospheric CO₂ from the geological past, through the industrial era, and considers possible changes in the future. It looks at the relevant controls on atmospheric CO₂ in the atmosphere, terrestrial biosphere, and in the ocean on timescales of years to centuries.

Introduction

Carbon dioxide (CO₂) is considered a trace gas in the atmosphere, with contemporary concentrations approaching 400 parts per million (ppm) by volume. Despite its low concentrations relative to those of nitrogen or oxygen, CO₂ plays a significant role in the Earth's life cycle and in controlling the global climate.

CO₂ is released as a by-product of aerobic respiration. Plants take up CO₂ and release oxygen as a part of photosynthesis. Variations in the global balance between photosynthesis and respiration result in seasonal variations in atmospheric CO₂ of up to 15 ppm. For example, atmospheric CO₂ concentrations in the Northern Hemisphere are generally lower in the summer, when many plant species enter a new growth stage and photosynthesis predominates over respiration. CO₂ is also a greenhouse gas that absorbs long-wavelength radiation in the atmosphere, attenuating its escape into space. The trapping of radiation by CO₂ and other greenhouse gases (e.g., water vapor, methane, nitrous oxide, and chlorofluorocarbons) helps keep Earth warmer than it would be without an atmosphere. It is this greenhouse warming that makes life, as we know it, possible on Earth.

Mankind is currently in the process of altering the chemistry of the global atmosphere. Atmospheric CO₂ concentrations have been increasing as a direct result of human activities such as deforestation and the burning of fossil fuels (e.g., coal and oil). Over the past 150 years, CO₂ concentrations in the atmosphere have increased by as much as 40% (from 280 to 392 ppm in 2012; [Figure 1](#)). This has been accompanied by an increase in global mean surface temperature of between 0.65 and 1.06 °C. The present rate of increase in CO₂ is unprecedented over the last 22 000 years.

This article briefly describes the complicated role that CO₂ plays on Earth, the different pools where carbon is stored, and the ways in which carbon is transferred between pools over various periods. We will focus on those pools (reservoirs) and transfers (fluxes) with timescales relevant to the human alteration of the natural carbon cycle. In addition, scientific issues relevant to future atmospheric CO₂ concentrations will be discussed along with a brief introduction to some of the global policy issues regarding regulation of future CO₂ emissions.

Figure 1 CO₂ concentrations in Antarctic ice cores (symbols) and annual mean concentrations from direct atmospheric measurements (line) for the past millennium. Prior to the industrial revolution atmospheric CO₂ values were very near 280 ppm. For the past 150 years, atmospheric concentrations have been increasing exponentially. Carbon and other biogeochemical cycles (Chapter 6). In: Stocker, T., Qin, D., Plattner, G.-K. (Eds.), *Climate Change 2013: The Physical Science Basis*. Cambridge University Press, Cambridge.

Geological History of Atmospheric CO₂

Atmospheric CO₂ varied considerably over the Earth's early history. The balance of several geochemical processes, including organic carbon and calcium carbonate burial, silicate rock weathering, and volcanism, controls the concentration of atmospheric CO₂ over long (millennial) timescales. When one process dominates over the others, such as during intensified periods of active volcanism, atmospheric CO₂ concentrations can change significantly over time. For example, during times of high volcanism in the Jurassic period about 200–150 Ma, CO₂ concentrations in the atmosphere rose to more than 3000 ppm. The high CO₂ levels made the rain more acidic by reacting with the water to form carbonic acid. The high acid content of the rainwater eventually caused higher rates of chemical breakdown (weathering) in carbonate and silicate rocks, releasing basic ions (e.g., bicarbonate and silicate). These basic ions traveled via rivers and groundwater to the oceans, eventually increasing the

ocean's capacity to absorb CO_2 from the atmosphere. The patterns of the large-scale geological processes and the responses of the global carbon cycle during the early stages of the Earth's history caused large swings in atmospheric CO_2 .

The relatively high atmospheric CO_2 concentrations present over most of the Earth's history were substantially decreased with the evolution of terrestrial vegetation and the subsequent enhancement of silicate weathering from the decomposition of plant matter in soils. For approximately the past 20 My, the geochemical evidence from the sedimentary record suggests that CO_2 concentrations in the atmosphere remained below 300 ppm until the beginning of the twentieth century. Recent studies of CO_2 trapped in air bubbles preserved in ice cores from Greenland and Antarctica have provided scientists with high-resolution records of atmospheric CO_2 concentrations for the past 800 000 years. The longest record, from the Vostok ice cores in Antarctica, shows that atmospheric CO_2 fluctuations were only about 100 ppm, associated with transitions from glacial to interglacial periods (Figure 2). The Vostok ice core record, which spans four glacial-interglacial cycles, reveals that atmospheric CO_2 was low (~ 180 ppm) during the glacial periods and high (~ 280 ppm) during the interglacial periods. Natural changes in the global carbon cycle between glacial and interglacial periods have maintained the atmospheric CO_2 levels between these two extremes for at least the past million years.

Controls of Modern Atmospheric CO_2

There are only three major reservoirs with exchange rates fast enough to vary significantly on the timescale of decades to centuries: the atmosphere, the terrestrial biosphere, and the oceans. Of this three-component system, approximately 93% of the carbon is located in the oceans. The atmosphere, at about

830 Pg C ($1 \text{ Pg} 10^{15} \text{ g}$), has the smallest total pool of carbon. The annual atmospheric exchange of CO_2 with both the oceans and the terrestrial biosphere is on the order of ~ 200 Pg C per year. Although these fluxes are very large, the mass of carbon in each of these reservoirs may not change over time. Ice core records suggest that the atmospheric CO_2 concentrations were very close to 280 ppm for more than 1000 years prior to the industrial era (see Figure 1). This constancy suggests that the carbon pools were more or less in equilibrium, and the net transfer over sufficiently large areas was close to zero.

Atmosphere

Of the three rapidly exchanging major carbon pools, the atmosphere is the most well mixed. Since most of the current CO_2 sources to the atmosphere are in the Northern Hemisphere and CO_2 exchange across the Equator is estimated to take about 1 year, the CO_2 concentrations in the north are higher than in the southern latitudes (Figure 3). The fact that most of the terrestrial biosphere is located in the Northern Hemisphere also results in larger seasonal variations relative to the Southern Hemisphere. Data from the present Global CO_2 Atmospheric Sampling Stations (Figure 4) indicate that distinct CO_2 sources and sinks are difficult to identify by examining atmospheric concentrations alone because the CO_2 is quickly distributed around the globe by the winds. East-west gradients of atmospheric CO_2 concentration are an order of magnitude smaller than north-south gradients. CO_2 concentrations over the continents are only a few ppm higher than corresponding locations over the oceans.

Terrestrial Biosphere

Every year approximately 18% of the CO_2 in the atmosphere is cycled through terrestrial plants. This amount of carbon, or

Figure 2 Compilation of the European Project for Ice Coring in Antarctica (EPICA) Dome C CO_2 ice core record and temperature anomaly over the past 800 000 years. High-resolution carbon dioxide concentration record 650,000–800,000 years before present. *Nature* 453, 379–382. <http://dx.doi.org/10.1038/nature06949>.

Figure 3 Three-dimensional representation of changes in the latitudinal distribution of atmospheric carbon dioxide as a function of time. CO₂ concentrations increase from south to north. The surface shows greater variability in the northern latitudes because of seasonal changes in the terrestrial biosphere. The increase in CO₂ concentration with time is the result of anthropogenic emissions. Data are from the National Oceanic and Atmospheric Administration's Earth System Research Laboratory (NOAA/ESRL) Global Monitoring Division cooperative air sampling network.

about 120 Pg C, is converted every year to carbohydrates and plant material during photosynthesis. About half of this material forms plant tissue (leaves, stems, roots, and wood) and the other half is returned to the atmosphere by autotrophic respiration (CO₂ released by the plants). Global net primary production (NPP, photosynthesis–autotrophic respiration) is estimated to be approximately 60 Pg C per year. Of this amount, approximately 83% is returned to the atmosphere via heterotrophic respiration (decomposition of plant material by bacteria, fungi, and herbivores) and combustion due to forest fires. The carbon that remains is called the net ecosystem

production. Estimates of changes in carbon stocks by the US Forest Service suggest that about 10 Pg C per year is fixed into new plant matter globally every year. The net ecosystem production suffers further losses of carbon from harvesting and erosion of soil carbon and plant materials that are eventually transported via streams to rivers, and to the oceans. What remains behind, the net biome production, is the amount of carbon that is accumulated by the terrestrial biosphere every year. It is this carbon that is ultimately lost from the atmosphere as a terrestrial sink. Estimates of the net biome production averaged 0.2 Pg C per year (i.e., small net carbon

uptake from the atmosphere) during the decade of the 1980s and 1.0 Pg C per year in the decade of the 1990s.

Oceans

The oceans are the largest of the three main CO₂ reservoirs, containing about 50 times more CO₂ than the atmosphere and 19 times more than the terrestrial biosphere. On an annual basis, the two-way exchange of CO₂ between the atmosphere and the surface ocean is approximately 80 Pg C per year. Net exchange of CO₂ occurs by diffusion when there is a difference in the CO₂ partial pressure ($p\text{CO}_2$) between the atmosphere and oceans. For example, when the atmospheric $p\text{CO}_2$ is higher than the surface ocean, CO₂ diffuses across the air-sea boundary into the oceans. The oceans are able to hold much more carbon than other reservoirs because most of the CO₂ that diffuses into the oceans reacts with the water to form carbonic acid and its dissociation products, bicarbonate and carbonate ions. The conversion of dissolved CO₂ to bicarbonate and carbonate ions effectively reduces the $p\text{CO}_2$ in the water, promoting more diffusion from the atmosphere.

The oceans are mixed much more slowly than the atmosphere, so there are large horizontal and vertical gradients in CO₂ concentration. For more than 40 years, marine scientists have been measuring the distribution of $p\text{CO}_2$ in the surface waters of the oceans. A summary of the global data set is presented in Figure 5. CO₂ uptake from the atmosphere was generally found to occur in the high-latitude oceans as a result of two factors. First, CO₂ is more soluble in cold water, so as ocean currents (such as the Gulf Stream) transport water from the tropics to the poles they are cooled and can absorb more

CO₂ from the atmosphere. Second, the high-latitude zones are also regions where intermediate and bottom waters are formed. As the waters are cooled, they become denser and sink into the ocean's interior taking with them the CO₂ accumulated at the surface. This process of transporting CO₂ from the surface ocean to the deep because of the cooling and sinking of water masses is known as the solubility pump.

Another process that transfers CO₂ away from the surface ocean is termed the biological pump. Photosynthetic production of marine plants (phytoplankton) incorporates CO₂ and nutrients from seawater into living plant tissue and detritus. Microscopic marine animals, called zooplankton, consume the phytoplankton and provide the basis for the food web for all animal life in the sea. The gross primary production by marine phytoplankton is estimated to be about 110 Pg C per year. Most of this carbon is recycled in the upper ocean via autotrophic respiration, similarly to what occurs on land. Some of the organic carbon is transformed into dissolved organic carbon that is transported by currents and diffusion to deeper depths and oxidized by marine bacteria. The remainder of the organic carbon sinks as particulate matter. The downward transport of dissolved organic carbon, particulate organic carbon, and detritus makes up the bulk of the downward export flux of carbon into the ocean interior. Estimates of this global export production range from 10 to 20 Pg C per year. Heterotrophic respiration converts most of this organic carbon back into dissolved inorganic carbon (dissolved CO₂, bicarbonate, and carbonate) at depth. Only about 0.1 Pg C per year reaches the seafloor to be buried in the sediments. The CO₂ that is recycled at depth is slowly transported large distances by currents to areas where the waters return to the surface

Figure 5 Climatological map of seawater $p\text{CO}_2$ -atmospheric CO₂ (µatm) for the year 2000. Red and yellow regions indicate areas where CO₂ is transferred from the ocean to the atmosphere. Blue and purple regions indicate where CO₂ is entering the ocean. Climatological mean and decadal change in surface ocean $p\text{CO}_2$, and net sea-air CO₂ flux over the global oceans. *Deep-Sea Research II* 56 (8–10), 554–577. <http://dx.doi.org/10.1016/j.dsr2.2008.12.009>.

(upwelling regions). When the waters regain contact with the atmosphere, the CO₂ originally sequestered by the phytoplankton is returned to the atmosphere. This re-equilibration process helps to regulate atmospheric CO₂ concentrations over decadal and longer timescales. The major upwelling regions are along the equatorial belt, the Antarctic Circumpolar region, and various localized coastal upwelling regions. It is this biological pump that primarily maintains the strong vertical gradient of dissolved carbon in the oceans.

CO₂ in the Industrial Era

Vast amounts of carbon are stored in the Earth's crust as coal, natural gas, and oil. If not for the mining activities of mankind, this carbon would not be recycled back into the atmosphere for millennia. Combustion of coal, natural gas, and oil released an estimated 5.5 Pg C per year into the atmosphere in the decade of the 1980s, 6.4 Pg C per year in the 1990s and 7.8 Pg C per year during the first decade of this century (Table 1). Other human activities, such as cement manufacturing, also contribute significant quantities of CO₂ into the atmosphere every year. CO₂ generated as a direct result of human activities is called anthropogenic CO₂. The release of anthropogenic CO₂ increased the atmospheric concentrations on average by 2.0 ± 0.1 ppm every year over the last decade. This increase has been well documented since the 1950s by direct atmospheric measurements in locations such as Mauna Loa, Hawaii, that are well away from the primary CO₂ source regions (Figure 6).

Annual assessments of fossil fuel consumption are compiled for each country. By estimating the CO₂ released by each fuel type, one can estimate the total CO₂ released to the atmosphere each year. One intriguing finding of the atmospheric CO₂ sampling program is that only about half of the anthropogenic CO₂ released each year remains in the atmosphere. The exact mechanisms and locations for the remaining anthropogenic CO₂ sinks has been a matter of intense research for the past few decades. It is important to note that, in order to qualify as a sink for anthropogenic CO₂, the fluxes must be enhanced over preindustrial rates. CO₂ fluxes associated with the ocean's biological pump, for example, are 10–20 Pg C per year. There is no conclusive evidence, however, that these rates

have changed in the open ocean as a result of increased atmospheric CO₂. The growth of marine phytoplankton is generally limited by the availability of nutrients in the waters, not by carbon availability. In this case, although the fluxes associated with the biological pump are roughly twice the fossil fuel signal, the biological pump is not believed to be a significant sink for anthropogenic CO₂. The difficulty with determining exactly where the anthropogenic CO₂ is stored is that the Earth systems are very complex and the anthropogenic CO₂ signal is small relative to the natural fluxes. Scientists attribute the majority of the anthropogenic CO₂ removed from the atmosphere to uptake by the terrestrial biosphere and the ocean's solubility pump.

Terrestrial Biosphere

Human activities, particularly in the northern temperate and tropical forests, directly affect net biome production by changing agricultural practices, deforestation and reforestation practices, nitrogen fertilization practices, and CO₂ fertilization of land plants via increasing atmospheric CO₂ concentrations. Estimation of carbon stocks in terrestrial ecosystems requires an accurate knowledge of land cover, carbon density in vegetation and soils, and the fate of the plant carbon (e.g., burning, decomposition). Global estimates of the net terrestrial CO₂ sink via annual carbon stock changes have very large uncertainties. Scientists believe that the terrestrial biosphere is currently a global sink for carbon despite large releases of carbon as a result of deforestation (Table 1).

Deforestation has been responsible for almost 90% of the estimated emissions due to land-use change since 1850, with a 20% decrease of the global forest area. Conversion of natural vegetation to agriculture has also been a major source of CO₂, not only because of plant biomass loss but also from increased decomposition of soil organic matter caused by disturbance and the energy costs of various agricultural practices. However, these losses can be minimized with proper land management and the use of high-yielding plant varieties.

All trees, nearly all plants from cold climates, and most agricultural crops respond to increasing atmospheric CO₂ levels by enhancing their photosynthetic uptake of carbon. Experiments have shown an average increase in NPP of 20–25% for a doubling of atmospheric CO₂. Increased uptake, particularly in temperate climates, can serve to counteract the CO₂ release due to land-use practices like deforestation. However, experiments on some plant species have shown a diminishing or lack of CO₂ fertilization effect in some ecosystems; likely due to nitrogen or phosphorus limitation. Nitrogen limitation appears to be prevalent in temperate and boreal ecosystems while phosphorus limitation dominates in the tropics. Research also suggests that inputs of nitrogen from human activities may also help to increase NPP rates in some areas. Thus, increases in the uptake rate of the terrestrial biosphere due to CO₂ fertilization have large uncertainties at this time.

Ocean Solubility Pump

The constancy of atmospheric CO₂ concentrations in the centuries prior to the industrial revolution suggests that the

Table 1 Global CO₂ budgets (in Pg C per year) for the last three decades based upon atmospheric CO₂ and O₂ data^a

Source or sink	1980–89	1990–99	2000–09
CO ₂ emissions (fossil fuel, cement product)	5.5 ± 0.4	6.4 ± 0.5	7.8 ± 0.6
Atmospheric increase	3.4 ± 0.2	3.1 ± 0.2	4.0 ± 0.2
Ocean–atmosphere flux	–2.0 ± 0.7	–2.2 ± 0.7	–2.3 ± 0.7
Land–atmosphere flux	–0.1 ± 0.8	–1.1 ± 0.9	–1.5 ± 0.9

^aPositive values represent fluxes to the atmosphere; negative values represent uptake away from the atmosphere. The land–atmosphere flux represents the net balance of a positive term due to land use changes and a negative term due to a residual carbon sink.

Figure 6 Monthly mean atmospheric CO₂ concentrations from Mauna Loa, Hawaii, sampling station. Data prior to May 1974 are from the Scripps Institution of Oceanography (SIO). Data since May 1974 are from NOAA/ESRL. The monthly trend curve illustrates the magnitude of the seasonal cycle at this latitude. While the seasonal range has been relatively constant, the long-term trend curve clearly shows the annual increase in atmospheric CO₂. Figure provided by P. Tans, NOAA/ESRL.

Oceans were a small net source of CO₂ to the atmosphere to balance the carbon input from rivers. Today, the net oceanic flux has been reversed because of anthropogenic inputs of CO₂ to the atmosphere. A global average air–sea difference of 8 ppm would result in a net flux of approximately 2 Pg C per year. The uptake of anthropogenic CO₂ by the oceans is driven by the thermodynamic forcing from the air–sea difference in $p\text{CO}_2$ and the air–sea transfer velocity. The transfer velocity is related to the surface roughness of the ocean and the wind speed. The thermodynamic forcing is related to the amount of CO₂ that is converted from $p\text{CO}_2$ to other carbon species in the seawater, such as bicarbonate and carbonate ions. This so-called buffer capacity is what allows the oceans to hold so much carbon. The relative concentrations of dissolved CO₂ (1%), bicarbonate ion (91%), and carbonate ion (8%) control the acidity (pH) of the oceans. Since CO₂ is an acid gas, the uptake of anthropogenic CO₂ consumes carbonate ions and lowers the oceanic pH in a process called ocean acidification. The carbonate ion concentration of surface seawater in equilibrium with the atmosphere will decrease by about 28% with a doubling of atmospheric CO₂ from preindustrial levels (from 280 to 560 ppm). As the carbonate ion concentration decreases, the buffer capacity of the oceans and its ability to further absorb CO₂ from the atmosphere is reduced.

Future CO₂ Concentrations

Coupled Atmosphere–Ocean General Circulation Models (AOGCMs) have long been used for making climate projections. Model runs coordinated through the 5th Coupled Model Intercomparison Project (CMIP5) form the core of the projections section of the Intergovernmental Panel on Climate Change (IPCC) 5th Assessment Report. Many of the AOGCMs used in CMIP5 now have an interactive carbon cycle; that is components of land and ocean biogeochemistry respond to changes in the

climate conditions to influence atmospheric CO₂ concentrations. These models provide an important predictive link between fossil fuel CO₂ emissions, future CO₂ concentrations and climate.

The carbon cycle response to future climate and CO₂ changes can be viewed as two strong and opposing feedbacks: climate and CO₂ concentration. Changes in climate generally lead to decreases in carbon storage while increases in atmospheric CO₂ generally lead to larger carbon storage. On a global scale, models agree on the sign of ocean and land response to increasing CO₂ and climate change, but do not agree on the magnitude of the changes.

The models generally agree that tropical ecosystems will store less carbon in a warmer climate while at high latitudes warming will increase storage of carbon in trees. It should be noted, however, that limitations in forest growth due to nitrogen availability and a loss of carbon from the decomposition of permafrost are generally not accounted for in the models. Models suggest that ocean carbon storage will continue to increase as long as atmospheric CO₂ continues to rise. However, warming and circulation changes will reduce the rate of carbon uptake in the ocean, particularly in the Southern Ocean and North Atlantic.

Carbon Sequestration Efforts

Over the long term (millennial timescales), the ocean has the potential to absorb approximately 85% of the anthropogenic CO₂ that is released to the atmosphere. As long as atmospheric CO₂ concentrations continue to rise, the oceans will act as a sink. However, this reaction is reversible. If atmospheric CO₂ were to decrease in the future, the oceans would start to release the accumulated anthropogenic CO₂ back out into the atmosphere. The ultimate sinks for anthropogenic CO₂ must be reactions that bind the CO₂ in a manner that is not easily reversed. Weathering of silicate rocks on land, for example, is a long-term sink for CO₂.

Carbon burial into the sediments can also provide a long-term sink. One proposed approach for enhancing carbon removal from the atmosphere is to enhance phytoplankton production by fertilizing specific regions of the ocean with micronutrients such as iron that are currently limiting production. The hypothesis is that the resulting bloom of oceanic plants would remove CO₂ from the atmosphere then transport that carbon into the deep ocean or sediments, effectively removing it from the short-term budget. The effectiveness of the 'iron hypothesis' is currently being studied. Other carbon sequestration approaches, including direct injection of liquefied CO₂ into the deep ocean, are also being examined. Further research is necessary to determine whether any of these techniques will be effective or economically feasible. Implementation of these approaches may depend, in large part, on policy decisions made on national and international levels.

Efforts to Reduce CO₂ Emissions – The Kyoto Protocol and Beyond

During the Earth Summit in Rio de Janeiro in 1992, the United Nations established the Framework Convention on Climate Change (UNFCCC) to encourage member countries to stabilize greenhouse gas emissions at a level that will prevent dangerous interference with the global climate system. In 1997 a meeting was held in Kyoto, Japan, to establish legally binding commitments for reducing future emissions of CO₂ and other greenhouse gases. The goal was for each member country to set emission commitments so that by the period 2008–12 the overall global emissions will be reduced to 5% below the levels emitted in 1990. The time frame 2008–12 was set for compliance so that member nations could make the transition to efficient lower-emitting carbon technologies.

The Kyoto Protocols stipulated that if some member countries could enhance the Earth's natural carbon sinks, for example by enhancing the uptake of carbon into forests, these additional carbon 'sinks' could be used as part of their emission assessments. For countries with major forests, like the United States, Russia, and Canada, these enhanced carbon sinks could be used to counterbalance some small increases in CO₂ emissions. In addition, the Protocols allow for trading of these so-called carbon credits to take advantage of international trade agreements. Developing countries were assigned no emission commitments and developed countries were required to reduce their emissions by an average of 7% below their 1990 levels. One provision of the protocols allows developing countries to trade emission credits to developed countries in exchange for technology that enhances carbon uptake.

The Protocol entered into force in 2005 despite the fact that the United States signed, but did not ratify it. The Conference of the Parties (COP) is the supreme decision making body of the UNFCCC. They have continued to meet annually to discuss the implementation of the Convention, the Kyoto Protocol and any other legal instruments that the COP adopts. At the COP 17 meeting in Durban, South Africa at the end of 2011, the Protocol was amended to accommodate a second commitment period from 2013 to 2020, a new platform of negotiations

under the Convention was outlined for the period beyond 2020, and the long-term implementation of a global support network to deliver funding and technologies that help developing countries was launched. At the Warsaw Climate Change Conference (COP19) in 2013 decisions to further advance the 'Durban Platform,' the Green Climate Fund and the long-term financing of REDD plus (Reducing Emissions from Deforestation and forest Degradation in developing countries) were adopted.

Summary

Atmospheric CO₂ is an integral part of all life on Earth. It is not only involved in basic photosynthesis and respiration but also helps control the climate of the environment we live in. The global carbon cycle is very complex and not completely understood today. The gross fluxes associated with a number of processes have the potential to quickly alter the composition of the global atmosphere. The positive and negative feedback mechanisms associated with these processes appear to have been relatively well balanced for the period of mankind's existence. Today, however, human activities are serving to alter that balance. Attempts to regulate emissions at the international level have not had great success. Researchers are working to better understand how the global environment might be altered from the addition of anthropogenic CO₂ and other greenhouse gases to the atmosphere. At this point, a doubling of atmospheric CO₂ over preindustrial levels is almost inevitable. Recent changes observed in the global climate are consistent with the predicted response to increasing greenhouse gases in the atmosphere.

Synopsis

Feedbacks modify an initial warming of the climate system, caused, for example, by increasing carbon dioxide. We discuss here the feedbacks that are of primary importance on decadal timescales: the water vapor feedback, the lapse-rate feedback, the surface albedo feedback, and the cloud feedback. Together, they account for approximately two-thirds of the warming we expect over the twenty-first century. The strongest positive feedback is the water vapor feedback, with the surface albedo and cloud feedbacks being smaller, positive feedbacks. The lapse-rate feedback is a negative feedback that offsets some of the water vapor feedback. The cloud feedback is the most uncertain one, and it is responsible for much of the spread among climate models in predictions of future climate change.

Planetary Energy Balance

Using an energy-balance perspective, we can represent energy flows within the climate system with a simple difference equation:

$$H = \Delta F - \lambda \Delta T \quad [1]$$

where ΔT is the global average surface temperature anomaly (an anomaly is the departure from a predefined reference state) and H is the top-of-atmosphere (TOA) net energy imbalance. ΔF is the radiative forcing, which is an energy imbalance imposed on the Earth's climate system from, for example, changes in the Sun's intensity, the addition of aerosols from a volcanic eruption, or the addition of greenhouse gases to our atmosphere (Forster et al., 2007).

In response to the energy imbalance imposed by the forcing, the Earth's temperature will change in order to reestablish energy balance for the planet. Setting $H = 0$, we find that the equilibrium temperature change in response to the radiative forcing is:

$$\Delta T = \Delta F / \lambda \quad [2]$$

Thus, $1/\lambda$ is how much the climate system must warm per unit of radiative forcing, and it is one measure of what is commonly referred to as the climate sensitivity.

λ can be decomposed into a sum of terms:

$$\lambda = \lambda_0 + \sum \lambda_i \quad [3]$$

where λ_0 is the 'no feedback' response (discussed in The 'No Feedback' Response section) and λ_i are various feedbacks (discussed in Feedbacks section).

The 'No Feedback' Response

In order to define feedbacks, one must first define a 'no feedback' response: the response before any feedbacks have influenced the climate. The most common definition of the 'no feedback' response is a vertically uniform warming of the surface and atmosphere, with everything else – atmospheric water vapor, clouds, surface albedo, etc. – held constant (See **Climate and Climate Change: Greenhouse Effect**). This is frequently referred to as the Planck response (sometimes, it is

also referred to as the Planck feedback, although, technically, it should not be considered a feedback). Given this definition of a 'no feedback' response, changes in water vapor, lapse rate, clouds, and surface albedo in response to a warming surface, are all categorized as feedbacks.

We can make a very simple estimate of the magnitude of λ_0 by taking the derivative of the Stefan–Boltzmann relation, $d(\sigma T^4)/dT = 4\sigma T^3$, and evaluating it at 255 K, the effective radiating temperature of the Earth. This yields $-3.7 \text{ W m}^{-2} \text{ K}^{-1}$ (the sign convention is positive fluxes are downward, so negative numbers indicate that a warmer planet radiates more energy to space). What this means is that, everything being constant, an increase in the temperature of the Earth will increase the power the Earth radiates to space by 3.7 W m^{-2} per degree.

Table 1 lists more sophisticated estimates based on radiative transfer calculations and realistic climate variations. This includes estimates from reanalysis data sets (ERA-Interim (Dee et al., 2011) and NASA's Modern Era Retrospective-analysis for Research and Application (MERRA) (Rienecker et al., 2011)), which are constructed from observations. These mainly represent the system's response to short-term climate variations, such as the El Niño/Southern Oscillation (ENSO). λ_0 from these data are $-3.1 \text{ W m}^{-2} \text{ K}^{-1}$.

Table 1 also includes estimates from an ensemble of 13 fully coupled global climate models (GCMs). The first estimate is from preindustrial control runs of the ensemble – runs in which greenhouse gas abundances and other forcings are held constant at their preindustrial concentrations, so there is no long-term climate change. The climate simulated in this ensemble is also dominated by short-term climate variations, so it is comparable to the calculations based on the reanalyses. This ensemble produces an average λ_0 of $-3.1 \text{ W m}^{-2} \text{ K}^{-1}$, in good agreement with the reanalyses. Values for the individual models can be found in Table S1 of Dessler (2013).

λ_0 can also be calculated from twenty-first century runs of the ensemble driven by the A1B emissions scenario, a moderate greenhouse-gas emissions scenario in which the Earth warms by several degrees Celsius over the twenty-first century. This ensemble produces an average λ_0 of $-3.3 \text{ W m}^{-2} \text{ K}^{-1}$, reasonably close to the value based on short-term climate variations and close to previous calculations (Colman, 2003; Soden and Held, 2006). Given radiative forcing from doubled

Table 1 All quantities are in $\text{W m}^{-2} \text{K}^{-1}$

Feedback	ERA-Interim		MERRA		Control runs		A1B runs	
	Feedback	Uncertainty	Feedback	Uncertainty	Feedback	Uncertainty	Feedback	Uncertainty
<i>Standard breakdown</i>								
Planck feedback	−3.09	0.07	−3.12	0.08	−3.12	0.12	−3.27	0.03
Lapse rate	−0.17	0.46	0.29	0.58	0.03	0.59	−0.86	0.28
Water vapor	1.35	0.35	1.12	0.39	1.38	0.62	2.00	0.21
Albedo	0.28	0.15	0.24	0.15	0.30	0.12	0.28	0.09
Total cloud	0.49	0.69	0.58	0.70	0.81	0.31	0.58	0.44
LW cloud	0.46	0.42	0.24	0.47	0.46	0.40	0.59	0.23
SW cloud	0.02	0.78	0.34	0.74	0.36	0.35	0.00	0.59
Thermal damping rate	−1.15	0.88	−0.89	0.88	−0.60	0.37	−1.26	0.45
<i>Constant-RH breakdown</i>								
Planck/RH	−1.92	0.03	−1.92	0.04	−1.91	0.05	−1.90	0.01
Lapse rate/RH	0.09	0.20	0.26	0.26	0.14	0.27	−0.28	0.13
ΔRH	−0.08	0.27	−0.05	0.30	0.06	0.19	0.06	0.10

For the ERA-Interim and MERRA, the uncertainties are 2σ . For the control and A1B model ensembles, the feedback is the average of the model ensemble and the uncertainty is the standard deviation of the ensemble.

Reproduced from Dessler, A.E., 2013. Observations of climate feedbacks over 2000–10 and comparisons to climate models. *J. Clim.* 26, 333–342. <http://dx.doi.org/10.1175/jcli-d-11-00640.1>.

carbon dioxide of 3.7 W m^{-2} (Myhre et al., 1998), eqn [2] predicts that the amount of warming in the absence of feedbacks is 1.2°C .

Identifying that part of the total climate response that constitutes the ‘no feedback’ response is somewhat arbitrary, Held and Shell (2012) suggested an alternative definition: a uniform warming of the surface and atmosphere, but with water vapor mixing ratio increasing so as to maintain constant relative humidity (RH) (Ingram, 2010). Table 1 shows that this alternative ‘no feedback’ climate response has a magnitude of $-1.9 \text{ W m}^{-2} \text{K}^{-1}$.

This value is less negative than the standard Planck response because the water vapor mixing ratio increases as a planet warms in order to maintain constant RH. Because water vapor is itself a greenhouse gas, this increase in water vapor traps infrared radiation and reduces the ability of the planet to increase radiation as it warms – so it only emits an additional 1.9 W m^{-2} for every degree of warming. Note also that changing the ‘no feedback’ climate response will necessarily change the definition of the climate feedbacks.

Feedbacks

It is worth reviewing at this point the chain of events that produce climate change. It begins with an imposed radiative forcing ΔF , which alters the planetary energy balance. This causes an initial change in the surface temperature ΔT_i , the magnitude of which is set by the ‘no feedback’ response.

In response to this initial warming, changes in the climate system occur that can further influence the climate – these are the climate feedbacks. These feedbacks generate an additional temperature change of $g\Delta T_i$ (g is a measure of the gain or strength of the feedbacks). But feedbacks also operate on the warming $g\Delta T_i$, and this leads to additional warming of

$g(g\Delta T_i) = g^2\Delta T_i$. Also feedbacks operate on this additional warming, leading to an additional warming of $g^3\Delta T_i$, etc. This goes on forever, so the final warming ΔT_f is

$$\Delta T_f = \Delta T_i + g\Delta T_i + g^2\Delta T_i + g^3\Delta T_i + g^4\Delta T_i \dots \quad [4]$$

This infinite series can be rewritten more simply as:

$$\Delta T_f = \frac{\Delta T_i}{(1 - g)} \quad [5]$$

The parameter g can be either positive or negative. Negative values of g correspond to feedbacks that ameliorate an initial temperature increase, and these are referred to as negative feedbacks. Positive values of g correspond to feedbacks that amplify the initial warming, and these are referred to as positive feedbacks. Note that $g > 1$ corresponds to ‘runaway’ greenhouse warming, where the warming from feedbacks outstrips the ability of the ‘no feedback’ response to shed energy (Roe, 2009). In such a situation, warming eventually ceases due to fundamental limitations in the feedbacks. For example, the ice-albedo feedback ceases when all of the ice on the planet has melted away, while the water vapor feedback eventually runs out of steam after the oceans boil away.

Equations [2] and [5] are equivalent if one recognizes that $\Delta T_i = \Delta F/\lambda_0$ and $1 - g = 1 + \frac{1}{\lambda_0} \sum \lambda_i$. λ_i is the strength of feedback i , and it has units of $\text{W m}^{-2} \text{K}^{-1}$. One can think of λ_i as a measure of how much this process alters TOA net flux per unit of surface warming. Putting this together, $g = -\frac{1}{\lambda_0} \sum \lambda_i$, so it is the sum of the individual λ_i 's divided by λ_0 .

The Water Vapor Feedback

The water vapor feedback is the process whereby an initial warming of the planet, caused, for example, by an increase in

atmospheric carbon dioxide, leads to an increase in the humidity of the atmosphere. Because water vapor is itself a greenhouse gas, this increase in humidity traps energy before it can escape to space, leading to additional warming. But not all regions of the atmosphere contribute equally: the water vapor feedback mainly results from changes in humidity in the tropical upper troposphere (Held and Soden, 2000), where temperatures are far below that of the surface and the vapor is mostly above clouds.

It had initially been argued that understanding tropical water vapor would be difficult because of the interaction between large-scale processes (e.g., the Hadley and Walker circulations) and small-scale processes (e.g., microphysics of clouds) (Emanuel and Pierrehumbert, 1995; Rennó et al., 1994). There was even the suggestion that microphysical effects could actually lead to a drying of the free troposphere as the climate warmed (Lindzen, 1990).

Subsequent research, however, demonstrated that the distribution of humidity in the climatologically important tropical upper troposphere is well reproduced by ‘large-scale control’ models, in which air leaves stormy regions in a saturated condition, but with negligible ice or liquid content. Water vapor is thereafter transported by the large-scale circulation, which conserves the specific humidity, except during subsequent saturation events, when loss of water occurs instantaneously to prevent supersaturation. Despite the simplicity of this idea, which entirely neglects detailed microphysics and other small-scale processes, such models accurately reproduce the observed water vapor distribution for the mid and upper troposphere (Sherwood, 1996; Dessler and Sherwood, 2000; Folkins et al., 2002; Pierrehumbert et al., 2007; Dessler and Minschwaner, 2007).

It has long been expected (Manabe and Wetherald, 1967) that the atmosphere’s RH would remain roughly constant – meaning that the specific humidity would exponentially increase with a warming climate. Minschwaner and Dessler (2004) created a simple radiative–convective model with interactive water vapor that showed how the couplings between the moistening effects of convective detrainment and the drying effects from clear-air subsidence, constrained by a balance between adiabatic warming and radiative cooling, produces a near constant, but slightly declining RH as the climate warms. Climate models also reproduce the slight reduction in RH in the tropical mid to upper troposphere as the climate warms (Soden and Held, 2006).

The first observational estimates of the water vapor feedback tested whether the atmosphere did indeed preserve constant RH during climate variations due to volcanic eruptions (Soden et al., 2002), ENSO and associated short-term internal climate variations (e.g., Minschwaner and Dessler, 2004), and decadal climate change (Soden et al., 2005). These analyses all concluded that RH is nearly conserved during these climate variations, confirming a strongly positive water vapor feedback.

More recently, the magnitude of the water vapor feedback, λ_{wv} , has been quantified as the change in TOA net energy flux due to the increase in water vapor per degree of surface warming. Observational estimates of λ_{wv} based on a volcanic eruption (Forster and Collins, 2004) and ENSO variations (Dessler et al., 2008; Dessler and Wong, 2009; Dessler 2013)

indicate that λ_{wv} is in the range 1.0–2.0 W m^{−2} K^{−1}. These latter three studies used off-line radiative transfer calculations (so-called radiative kernels (Soden et al., 2008; Shell et al., 2008)), which have become a popular method of calculating feedbacks.

The water vapor feedback has also been calculated in GCMs in response to short-term climate variations and in response to long-term warming. In response to short-term climate variations, λ_{wv} in GCMs is $\sim 1.1\text{--}1.3$ W m^{−2} K^{−1} (Colman and Power, 2010; Dessler, 2013), while that in response to long-term warming is 1.8–2.0 W m^{−2} K^{−1} (Colman and Power, 2010; Dessler, 2013; Colman, 2003; Soden and Held, 2006). These values are summarized in Table 1.

Thus, the water vapor feedback cancels some of the increased outgoing longwave radiation due to warmer atmospheric and surface temperatures. The net result is that, for a given radiative forcing, the Earth has to warm more in order to reestablish energy balance with the water vapor feedback than without. In this way, the water vapor feedback amplifies an initial warming, making it a positive feedback.

Comparisons between GCMs and observations show that some GCMs have large biases in their simulated present-day water vapor fields (John and Soden, 2007). Thus, it may be surprising that the GCMs generally agree among themselves and with observations on the value of the water vapor feedback (although some differences do exist, as described later). It turns out that the absorption of longwave radiation by water vapor is proportional to the logarithm of the amount of water, so it is the fractional changes in water vapor that determine the strength of the water vapor feedback – and all GCMs simulate similar fractional changes in the water vapor field as the surface warms (John and Soden, 2007). This occurs because tropospheric water vapor in the tropical upper troposphere is set by the temperature of convective detrainment through the Clausius–Clapeyron relation, which is a fundamental physical relation that all climate models incorporate.

Lapse-Rate Feedback

The standard ‘no feedback’ climate response is a uniform warming of the surface and atmosphere. However, the atmosphere’s temperature can also change relative to the surface, and such changes constitute the lapse-rate feedback. For example, the temperature of the tropics generally follows a moist adiabat set by the surface temperature; thus we expect the upper troposphere to warm about 2–3 times as much as the surface (Xu and Emanuel, 1989; Holloway and Neelin, 2007).

The enhanced radiation from the warmer upper troposphere enhances radiative cooling to space compared to the ‘no feedback’ response. Thus, the decrease of the lapse rate tends to reduce the initial temperature perturbation, leading to a negative feedback. In response to long-term warming, λ_{lr} in GCMs is -0.9 W m^{−2} K^{−1} (Colman and Power, 2010; Dessler, 2013; Soden and Held, 2006). Values of λ_{lr} during short-term climate variations (from both models and the reanalyses) are much closer to zero (Colman and Power, 2010; Dessler, 2013). These values are listed in Table 1.

The Connection between the Water Vapor and Lapse-Rate Feedbacks

There is some variation in the magnitude of the water vapor feedback among the GCMs (Colman, 2003; Soden and Held, 2006; Dessler, 2013). The cause of this is differences among the models in the amount of upper tropospheric warming per unit of surface warming (John and Soden, 2007), which fundamentally controls upper tropospheric water vapor through the Clausius–Clapeyron relation (Minschwaner and Dessler, 2004).

Thus, a model whose upper troposphere warms more than the ensemble average will have a positive water vapor feedback that is larger than the ensemble average. The warmer upper troposphere also radiates more power to space, so this model will also have a more negative lapse-rate feedback than the ensemble average. These effects largely cancel – so that the sum of the water vapor and lapse-rate feedbacks shows much less spread among the models than either feedback individually (Colman, 2003; Soden and Held, 2006).

Magnitudes of both the (positive) water vapor and (negative) lapse-rate feedbacks are smaller for short-term variability than for long-term climate change in climate models (Table 1). However, for reasons discussed above, the sum of the water vapor and lapse-rate feedbacks is similar for these two climate variations.

In the alternative breakdown of Held and Shell (2012), the ‘no feedback’ response and lapse-rate feedback both include a constant-RH assumption. Because the atmosphere nearly conserves RH in the global average, assuming constant RH essentially folds the water vapor feedbacks into these other terms. By combining the water vapor and lapse-rate feedbacks, this approach produces a new lapse-rate feedback that is more certain than in the standard breakdown. In addition, by eliminating the water vapor feedback, this alternative breakdown avoids having a large positive feedback (water vapor) canceling a large negative feedback (the lapse rate), which occurs in the conventional breakdown.

Surface Albedo Feedback

As the planet warms, the spatial coverage of ice and snow decreases, exposing the darker underlying surface. The resultant decrease in surface albedo (the ratio of reflected to incident solar radiation flux at the surface) increases the amount of solar radiation absorbed by the planet, thereby generating additional warming. This process therefore represents a positive feedback.

As feedbacks are defined at the TOA, one must relate the temperature-mediated change in surface albedo to that at the TOA (Hall and Qu, 2006):

$$\lambda_{\alpha} = \frac{dSW_{\alpha}}{dT} = SW_{in} \frac{d\alpha_s}{dT} \frac{\partial \alpha_p}{\partial \alpha_s} \quad [6]$$

where SW_{in} is the incident SW flux at the TOA, α_s is the surface albedo, and α_p is the planetary albedo. Thus, the surface albedo feedback depends on the incident solar radiation, the sensitivity of surface albedo to the change in global mean surface temperature, and the sensitivity of planetary albedo to changes in surface albedo. This final term is roughly 0.3 in both observations and models (Donohoe and Battisti, 2011), which

means that roughly 70% of the variations in surface albedo are hidden by overlying cloud cover and therefore do not impact the TOA energy budget.

In climate models, the global mean surface albedo feedback λ_{α} is roughly $0.3 \text{ W m}^{-2} \text{ K}^{-1}$ in response to long-term global warming (Soden et al., 2008; Vial et al., 2013); in response to short-term climate variations, both models and observations show a similar feedback strength (Dessler, 2013) (Table 1). Unsurprisingly, the surface albedo feedback primarily arises from changes in high latitudes (Crook et al., 2011), with about 75% coming from the Northern Hemisphere, with half from melting snow and half from melting sea ice (Winton, 2006). The remaining 25% comes from retreat of sea ice in the Southern Ocean. This is one of the reasons that high latitudes are expected to warm more than the tropics over the twenty-first century.

Intermodel differences in the sensitivity of the surface albedo to surface temperature ($d\alpha_s/dT$) are by far the dominant source of intermodel disagreement in surface albedo feedback, spanning a threefold range across models (Qu and Hall, 2006, 2014; Winton, 2006). Intermodel spread in the snow albedo feedback mainly arises from intermodel spread in the albedo decrease from reductions in areal coverage of snow, which itself is mainly attributable to the intermodel spread in mean effective snow albedo (Qu and Hall, 2007). Thus, models with a greater mean-state snow albedo generally experience a larger snow albedo feedback. Hall and Qu (2006) showed that the modeled response of Northern Hemisphere springtime snow albedo to temperature in the present-day seasonal cycle is an excellent predictor of its response to climate change, implying that this component of surface albedo feedback can be observationally constrained.

In a similar manner to the snow albedo feedback, the sea ice-albedo feedback depends strongly on the areal coverage and albedo of ice. Models with thinner mean-state sea ice tend to have larger sea ice-albedo feedbacks because thinner ice is easier to melt. Similarly, models with larger mean-state sea ice extents have more ice available to lose, and therefore tend to have larger sea ice-albedo feedbacks (Rind et al., 1995; Holland and Bitz, 2003).

Flanner et al. (2011) estimate a Northern Hemisphere surface albedo feedback between 0.3 and $1.1 \text{ W m}^{-2} \text{ K}^{-1}$ based on the observed decrease in surface albedo between 1979 and 2008, suggesting that current models are underestimating this feedback. Moreover, the observed decline in the spatial extent of Arctic sea ice at the end of the melt season between 1953 and 2006 is proceeding at a much faster rate than is predicted by any current climate models, also suggesting that sea ice cover may also be too insensitive to warming in the models (Stroeve et al., 2007).

Cloud Feedback

Clouds have a large impact on the Earth’s TOA energy budget, both in the longwave (LW, wavelengths >4 microns) and in the shortwave (SW, wavelengths <4 microns). These are commonly quantified using cloud radiative effect (CRE; Charlock and Ramanathan, 1985), which is the difference between clear-sky (R_{clear}) and all-sky (R_{total}) TOA upwelling flux:

$$CRE = R_{clear} - R_{total} \quad [7]$$

R_{clear} is the flux that would occur if clouds were instantaneously removed from the atmosphere, but all other parameters stayed the same. Also, note that CRE is sometimes referred to as cloud radiative forcing or CRF.

Breaking a scene into an overcast portion with area f and a clear portion with area $(1 - f)$, one can express the total upwelling radiation as:

$$R_{\text{total}} = fR_{\text{cloud}} + (1 - f)R_{\text{clear}} \quad [8]$$

where R_{cloud} is the TOA flux from the cloudy region. Combining [7] and [8] yields:

$$\text{CRE} = f(R_{\text{clear}} - R_{\text{cloud}}) \quad [9]$$

The LW, SW, and net CRE of idealized overcast scenes characterized by single-layer clouds with tops at various pressures and optical depths are shown in Figure 1. The greater the cloud fraction, or the greater the contrast in upwelling SW flux between clear and overcast locations (which depends on both the albedo contrast and the incident solar radiation), the greater the SW CRE. As cloud albedo is almost always larger than the clear-sky albedo, the SW CRE is negative, with a global and annual mean of roughly -50 W m^{-2} (Allan, 2011). Similarly, the greater the cloud fraction, or the greater the temperature difference between the surface and the cloud top (which depends primarily on the cloud-top height), the greater the LW CRE. One can therefore think of the LW CRE as measuring the greenhouse effect of clouds. Because most clouds are found at locations colder than the surface, the upwelling LW flux from clouds is almost always smaller than that from clear-sky regions, making LW CRE positive. In the annual and global mean, the LW CRE is roughly 30 W m^{-2} (Allan, 2011). Thus, the net effect of clouds is to cool the planet by roughly 20 W m^{-2} .

Cloud feedback is a measure of how much this cooling effect of clouds changes per unit increase in global mean surface temperature. A positive global mean cloud feedback means that the cooling effect of clouds decreases in magnitude as the planet warms. Because the effect of clouds on the SW reflectivity tends to dominate over the effect of clouds on the LW heating of the planet (i.e., net CRE is negative), temperature-mediated decreases in total cloud fraction holding their other properties fixed would represent a positive cloud feedback. All else being equal, temperature-mediated increases in cloud-top altitude (which reduces LW emission from clouds) and decreases in cloud optical depth (which reduces SW reflection more than it increases LW emission) are positive cloud feedbacks. A shift of clouds from regions having large values of insolation (low latitudes) to regions having lower values of insolation (high latitudes), holding all else constant, would also constitute a positive cloud feedback, as the amount of SW radiation reflected to space depends on the amount that is incident on the cloud. Conversely, temperature-mediated increases in total cloud amount, decreases in cloud-top altitude, increases in cloud optical depth, and shifts of clouds toward regions with larger incident solar radiation represent negative cloud feedbacks.

There are a wide variety of possible cloud responses to warming. The cloud feedback is unique among the climate feedbacks in that its net global mean value is the integrated effect of a multitude of processes that may oppose each other

Figure 1 Globally averaged and annually averaged (a) LW, (b) SW, and (c) net cloud radiative effects for completely overcast scenes containing clouds with given properties of cloud-top pressure (CTP) and cloud optical depth (τ). Cloud optical depth is plotted on a logarithmic scale due to the linear relationship between $\log(\tau)$ and albedo. In the LW, τ is a proxy for cloud emissivity. Figure modified from Zelinka, M.D., Klein, S.A., Hartmann, D.L., 2012a. Computing and partitioning cloud feedbacks using cloud property histograms. Part I: cloud radiative kernels. *Journal of Climate* 25, 3715–3735. <http://dx.doi.org/10.1175/jcli-d-11-00248.1>.

horizontally, vertically, in optical depth space, and spectrally. This level of complexity, in addition to the fact that clouds are parameterized rather than explicitly resolved in GCMs, makes it the most uncertain feedback operating in climate models, and persistently so. For a given radiative forcing, most of the spread among climate model predictions of future warming arises from intermodel differences in cloud feedback (Cess and Potter, 1988; Cess et al., 1990; Webb et al., 2006; Dufresne and Bony, 2008; Andrews et al., 2012; Vial et al., 2013).

Despite large intermodel disagreement in the exact magnitude of cloud changes, several features are robust. GCMs systematically predict a fairly spatially uniform increase in high cloud-top altitude that is likely related to deepening of the

well-mixed troposphere as the planet warms, causing an increase in LW trapping and a positive net cloud altitude feedback of roughly $0.3 \text{ W m}^{-2} \text{ K}^{-1}$ (Zelinka et al., 2012b; Zelinka et al., 2013). The tendency for tropical high clouds to systematically rise as the planet warms is grounded fairly strongly in theory (Hartmann and Larson, 2002), and is supported by cloud-resolving model experiments (Tompkins and Craig, 1999; Kuang and Hartmann, 2007; Harrop and Hartmann, 2012), GCM experiments (Zelinka and Hartmann, 2010), and observations (Zelinka and Hartmann, 2011; Li et al., 2012).

GCMs also robustly predict small decreases in cloud optical depth for warm clouds at low latitudes and large increases for cold clouds at high latitudes and high altitudes as the planet warms (Zelinka et al., 2012b; Zelinka et al., 2013). The latter may be related to the temperature-induced increase in total cloud water content, which is more sensitive at the cold temperatures characteristic of high latitude clouds (Betts and Harshvardhan, 1987), or to the preferential increase of liquid relative to ice at warmer temperatures, which results in brighter clouds (Tsushima et al., 2006). The negative feedback due to enhanced SW reflection from optically thicker clouds is negative in the global mean in the vast majority of current models, averaging about $-0.15 \text{ W m}^{-2} \text{ K}^{-1}$. It is the dominant cloud feedback at high latitudes.

In all current models, global average total cloud fraction systematically decreases as the planet warms, contributing a positive feedback of about $0.15 \text{ W m}^{-2} \text{ K}^{-1}$ because the changes in the SW dominate those in the LW (Zelinka et al., 2012b; Zelinka et al., 2013). The tendency for total cloud fraction to decrease at low latitudes and increase at high latitudes represents a positive feedback owing to the overall shift of clouds toward regions with less insolation. A portion of this pattern may be related to the poleward shift of the major circulation features (i.e., the relatively cloud-free subtropical dry zone expands and the cloudy midlatitude storm track region shifts poleward (Hall et al., 1994; Yin, 2005)). Despite most models predicting a decrease in the amount of subtropical marine boundary layer clouds in regions of moderate subsidence, subtle differences among models in the magnitude of this change, when weighted by the expansive coverage of these cloud types, translates into large intermodel differences in cloud feedback and climate sensitivity (Bony and Dufresne, 2005; Soden and Vecchi, 2011; Webb et al., 2013). Their properties are known to be sensitive to a multitude of processes including boundary layer turbulent fluxes, lower tropospheric stability, cloud-top entrainment, free-tropospheric subsidence, and cloud-top radiative cooling, some of which are parameterized, expected to change in warming world, and subject to considerable uncertainty.

Obtaining observational estimates of cloud feedback, though highly desirable, is difficult owing to the dearth of observational data of suitable length and/or quality for identifying the subtle responses of clouds to the limited amount of warming that has been realized in nature. The global mean net cloud feedback in response to short-term (interannual) fluctuations in nature is estimated to be $0.50 \text{ W m}^{-2} \text{ K}^{-1}$ with a 2σ uncertainty of $0.75 \text{ W m}^{-2} \text{ K}^{-1}$ (Dessler, 2010; Dessler and Loeb, 2013), which is in agreement with the ensemble average short-term cloud feedback in climate models (Table 1). The ensemble average cloud feedback in response to long-term

climate change is similar to the average short-term cloud feedback, but little cross-model correlation exists between the long-term and short-term cloud feedbacks (Dessler, 2010), so it is presently unclear whether the short-term cloud feedback has relevance for the feedback in response to long-term warming. While we cannot verify the long-term cloud feedback using observations, the agreement between the models and observations for the short-term cloud feedback provides some confidence in the models' long-term cloud feedback. Moreover, specific aspects of cloud responses to natural climate variability may be useful for testing physical mechanisms of cloud feedbacks to long-term climate change (Tselioudis et al., 1998; Clement et al., 2004; Zelinka and Hartmann, 2011).

Slow Feedbacks

The feedbacks discussed above are the so-called fast feedbacks, meaning that they affect the climate on timescales of a week (water vapor and temperature) to a few years (sea ice). There are other feedbacks, however, that operate on much longer timescales. For example, the melting of the earth's great ice sheets is a positive albedo feedback, but one that occurs on millennial timescales. The timescale and strength of carbon cycle feedbacks – e.g., a warming climate melts permafrost, leading to the release of more carbon dioxide – is unknown, but probably occurs on centennial timescales.

Probably the longest timescale feedback is the weathering thermostat. In this feedback, warmer temperatures lead to higher rates of precipitation and enhanced weathering of rocks. The weathering reaction removes carbon dioxide from the atmosphere and transports it into the ocean. The resulting reduction of carbon dioxide offsets the initial warming, leading to a negative feedback. The long-term cooling since the Eocene (over the last 50 million years) has been hypothesized to be the result of the reduction in carbon dioxide due to enhanced precipitation on rock newly exposed from the uplift of the Himalayas and Tibetan plateau. While this is clearly a powerful feedback, its million-year timescale means that it will not act to ameliorate global warming over the next century.

Overall, there is some evidence, based on events such as the Paleocene–Eocene Thermal Maximum, that these slow feedbacks are net positive (Zeebe et al., 2009). However, given the uncertainty in both the temperature and the forcing data for these deep-time events, such a conclusion should not be considered definitive.

Summary

In response to a forcing of the climate system, the temperature of the planet adjusts until the planet's energy balance is restored. How much warming is required per unit of radiative forcing is a measure of the climate sensitivity. And this climate sensitivity can be broken down into a 'no feedback' response and a set of climate feedbacks that amplify or ameliorate it.

Without any feedbacks, a doubling of carbon dioxide produces a warming of $\sim 1.2^\circ\text{C}$. Including feedbacks increases this to $\sim 3^\circ\text{C}$. Thus, feedbacks are responsible for the bulk of the warming that the Earth will experience over the next

century. Estimates of the magnitude of the individual fast feedbacks (those that respond on timescales of a few years or less) are listed in [Table 1](#). The water vapor feedback is the climate system's primary positive feedback, and by itself it roughly doubles the 'no feedback' warming. The albedo and cloud feedbacks are smaller, positive feedbacks. While the cloud feedback is small compared to the water vapor feedback, it is the most uncertain feedback and is responsible for much of the spread in climate models' predictions of the climate sensitivity. The lapse-rate feedback is negative, meaning that it partially offsets the warming from the 'no feedback' response and the other feedbacks.

There is some evidence that the strength of feedbacks may differ for short-term climate variability and long-term warming. It is the feedbacks in response to long-term warming that interest us the most (because they are key to estimating warming over the next century) – but, unfortunately, the lack of long-term observations means that we cannot calculate the long-term feedbacks from observations.

While uncertainties in our estimates of the feedbacks and the resulting climate sensitivities exist, our confidence in our overall understanding of these processes is generally high. This arises primarily from a convergence between observations and models and theoretical expectations. Confidence also comes from the stability of understanding. Our present understanding of climate feedbacks, as described here, is in good agreement with estimates made throughout the twentieth century, including the first comprehensive modern studies of climate sensitivity and feedbacks ([Hansen et al., 1984](#); [Zhang et al., 1994](#); [Colman and McAvaney, 1997](#)).

Climate Prediction: Empirical and Numerical

S Hastenrath, University of Wisconsin, Madison, WI, USA

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

In tropical climate prediction, three categories of approaches can be recognized: (1) empirical methods based on the combination of circulation diagnostics with statistical techniques, (2) numerical modeling, and (3) empirical but purely statistical procedures. It is desirable to pursue in parallel (1) and (2). By way of example, an overview is offered for five target regions: El Niño and the Southern Oscillation (ENSO), the Nordeste of Brazil, the West African Sahel, the boreal autumn rains of East Africa, and the Indian summer monsoon. Comparisons yield no advantage of numerical modeling over empirical approaches. ENSO contributes strongly to interannual climate variability in only limited regions of the tropics. Indispensable are the verification of forecast performance on an independent data set, the documentation and publication of the method, publication of the forecasts in real time, and continuous evaluation of forecasts.

Introduction

Attempts at climate prediction span more than a century, and a renewed interest has developed since the early 1980s. On theoretical grounds, it has been suggested that prospects for the prediction of annual variability should be better for the lower than the higher latitudes. Method development has been directed at a wide variety of regional targets, as illustrated in Figure 1. From experience, it seems more fruitful to pursue empirical and numerical modeling approaches concurrently. A 'code of good conduct' requires documentation of the method, assessment of method performance on an independent data set, and regular verification of real-time forecasts.

Methods

In the endeavors at climate prediction over the past two decades, three broad categories of approaches can be recognized: (1) empirical methods based on the combination of general circulation diagnostics and statistical techniques, (2) numerical modeling, and (3) empirical but purely statistical techniques, although there are combinations of and transitions between the categories. Categories (1) and (2) imply a diagnostic understanding of circulation mechanisms. In the empirically based approaches (1) and (3), a clear distinction must be made between the dependent portion of the record (or training period) from which the method was developed and the independent

data set reserved for the verification of forecast performance (verification period). An independent verification period is essential to protect against noise fitting, a severe risk especially where a large number of predictors is used after excessive screening. In category 2, verification of performance against observations over a couple of decades is also in order.

Approach 1 – general circulation and statistics – is illustrated in Figure 2. Studies of general circulation diagnostics are aimed at understanding the mechanisms of climate anomalies. On this basis, indices are selected that appear promising as predictors. Effective combinations of predictors and formulations of quantitative predictor–predictand relationships are ascertained by appropriate statistical methods, such as stepwise multiple regression (SMR), linear discriminant analysis (LDA), and neural networks. Other statistical procedures widely used include canonical correlation analysis (CCA), singular spectrum analysis (SSA), and empirical orthogonal function (EOF) analysis. The quantitative predictor–predictand relationship represents the prediction model. This then serves for calculating predictand values for a portion of the record that had not been used in the development of the prediction model. Quantitative comparison of the calculated versus the observed values of the predictand provides verification of forecast performance. The evolution from general circulation diagnostics to prognosis is exemplified by a series of papers on Brazil's northeast region, the Nordeste.

An understanding of the general circulation mechanisms of climate anomalies from empirical–diagnostic studies is also basic to approaching numerical modeling. This is exemplified

Figure 1 Orientation map showing the location of forecasting targets referred to in this article: India, eastern Africa, southern Africa, Sahel, Northeast Brazil (Nordeste), North Atlantic storms, El Niño and the Southern Oscillation, Australia, North America, and Europe.

Figure 2 Scheme of climate prediction based on general circulation diagnostics and statistics. Adapted from Hastenrath, S., 1995a. Recent advances in tropical climate prediction. *Journal of Climate* 8, 1519–1532.

for the Pacific Ocean's El Niño phenomenon in the progression from the pioneering empirical oceanographic work over the first diagnostic ocean numerical studies to the application of numerical models for the operational prediction of El Niño. Similarly, the application of general circulation models (GCMs) to seasonal rainfall forecasting for the West African Sahel and Brazil's Nordeste has a broad empirical–diagnostic basis. In approach (2), the prediction model is developed from basic circulation theory rather than from past observations as in approach (1). Accordingly, the separation into dependent and independent portions of the record (as for approaches (1) and (2)) does not arise. Values calculated from previously observed conditions are again compared with the observed predictand values for verification. In principle, there are prospects of coupling the atmosphere, ocean, and land surface portions of the system. Purely statistical techniques (approach (3)) may seem unsatisfactory because of the lack of insight into the circulation mechanisms involved. Some of these endeavors merit attention, however, because of their remarkable practical performance.

Regional Targets

Methods for the forecasting of interannual variability have been developed for numerous regions, especially in the low latitudes. A series of examples are addressed here, namely Indian monsoon, eastern and southern Africa, Sahel, Northeast Brazil (Nordeste), North Atlantic storms, El Niño and Southern

Oscillation (ENSO), Australia, North America, and Europe, as identified in Figure 1.

Indian Monsoon

Empirical–diagnostic research over more than a century has led to a considerable understanding of the general circulation mechanisms of Indian monsoon rainfall anomalies and to the identification of numerous viable predictors. These can be loosely grouped into three classes, pertaining to the upper-air flow over India, to 'heat low' development over southern Asia and the establishment of a meridional pressure gradient and cross-equatorial flow over the Indian Ocean, and to the Southern Oscillation (SO, a high phase defined by anomalously high and low pressure at Tahiti and Darwin), although there are interrelations between the three classes. Figure 3 illustrates two simple prediction models based on variously used predictors and SMR. Conspicuously absent in the prediction of the Indian monsoon rainfall anomalies is the use of numerical models in the operational work of the India Meteorological Department or in the published literature. This is all the more remarkable because the sustained empirical work has afforded a sound understanding of the functioning of the general circulation of the monsoon and has shown Indian monsoon rainfall anomalies to be amenable to prediction. Along with these overall encouraging prospects for Indian monsoon forecasting, the reservation should be noted that the performance of various predictors has been known to vary in

Figure 3 Prediction of all-India summer monsoon rainfall from two models, using as predictors the latitude position of a 500 hPa ridge along 75° E in April (L); April minus January pressure tendency at Darwin (DPT); and an index of January–February Northern Hemisphere temperature (NHT). Solid dots denote regressed values for years up to 1968 and forecast values from 1969 onward, as separated by the vertical broken line. Open circles indicate observed rainfall. Adapted from Hastenrath, S., 1995a. Recent advances in tropical climate prediction. *Journal of Climate* 8, 1519–1532.

the long term. Predictability was found to be high for the 1960s and 1970s, to be followed by drastically reduced performance in the 1980s, as is apparent in [Figure 3](#). Such changes in predictability should be seen in the context of decadal-scale evolutions in the general circulation setting, but the direct causalities await clarification. Numerical model applications to the prediction of Indian monsoon rainfall anomalies will have to face the decadal-scale changes in intrinsic predictability as an added challenge.

Eastern Africa

Eastern Africa features two rainy seasons centered on April–May and October–November, and only the latter is strongly (and inversely) related to the SO. On purely statistical grounds, it has been shown that a portion of the variance of boreal autumn rains is predictable from the Tahiti minus Darwin pressure index alone. The general circulation causes of eastern African rainfall anomalies are related to the SO through a combination of cooperative mechanisms, which most effectively function in the boreal autumn rainy season of eastern Africa: (1) Westerly winds along the Indian Ocean Equator are conducive to lower-tropospheric divergence over equatorial East Africa; in the high SO phase these are accelerated, especially in October–November owing to the anomalous eastward pressure gradient. (2) The Equatorial westerlies drive the Eastward Equatorial Jet in the upper hydrosphere, which entails cold water upwelling in the western extremity of the basin, where sea surface temperature (SST) further hydrostatically affects the zonal pressure gradient and thus feeds back into the equatorial westerly winds. (3) In addition, cold-water anomalies in the western Indian Ocean, most pronounced in October–November during the high SO phase, also suppress convection. (4) In the high SO phase, the Indian summer monsoon tends to be strong, leaving behind an anomalously cold western Indian Ocean, which in turn feeds into the mechanisms (1)–(3). These processes are strong and definite in October and November, when the equatorial westerlies correlate at -0.85 with the rains at the East African coast, but reveal themselves little in effective precursors. Relationships for April and May are weak.

Southern Africa

Various groups endeavor to forecast the austral summer rains of Southern Africa from purely statistical methods and more recently also by using numerical modeling. Rains tend to be more abundant during the high and cold SO phase. A better diagnostic understanding of the circulation mechanisms of rainfall anomalies is needed.

Sahel

The climate problems in the Sub-Saharan zone of West Africa are particularly complex because interannual variability is superimposed on drastic decadal-scale changes of rainfall. These share some common mechanisms involving variations of the meridional SST gradient in the tropical Atlantic Ocean and latitudinal displacements of the Intertropical Convergence Zone (ITCZ), as well as SST changes in the western Indian

Ocean, but the reasons for the persistence of the present drought conditions are not yet understood. Thus, it seems essential to separate year-to-year variations from trendlike developments, a challenge in terms of both general circulation mechanisms and the proper statistical treatment.

Real-time forecasts are published regularly. The Hadley Center of the UK Meteorological Office contributes forecasts from both empirical and numerical modeling approaches. The empirical method entails EOFs of SST, where the inter-hemispheric SST gradient in the tropical Atlantic is most important. Correlation between forecast and observed rainfall is around 0.6, mostly related to persistence. The numerical modeling has global SST as input, and correlations of predicted versus observed rainfall are between 0.3 and 0.6. The National Oceanic and Atmospheric Administration's (NOAA) Climate Prediction Center in the United States reports results from an empirical method using CCA on global SST and gridded rainfall data for Africa. Most important is the inter-hemispheric difference in SST anomalies, particularly in the Atlantic, and ENSO is not the dominating aspect of the relationship; correlation between predicted and observed rainfall is around 0.3. Thus, there are indications for a moderate predictability of Sahel rainfall anomalies. Given the peculiar evolution of the Sahel climate, closer attention to the contributions from year to year compared to trendlike developments seems desirable.

Northeast Brazil

Northern Northeast Brazil has its rainy season narrowly concentrated around March–April, when the near-equatorial trough reaches its southernmost position in the course of the annual cycle. Rainfall anomalies have a severe human impact, their general circulation mechanisms are definite and well understood, and they offer themselves as a prime target of opportunity for climate prediction. During drought years, the southward SST gradient in the tropical Atlantic is enhanced, the near-equatorial low-pressure trough and embedded wind confluence and ITCZ are displaced northward, and the North Atlantic trade winds are reduced while the cross-equatorial flow from the Southern Hemisphere is accelerated. Warm-water anomalies in the equatorial Pacific also tend to be associated with dry conditions in Brazil's Nordeste.

General circulation diagnostics combined with statistical techniques form the basis for effective prediction methods. In the work at the University of Wisconsin, the predictand is an index of the March–June rainfall in the northern Nordeste, constructed from a network of quality-controlled rain gauge stations with continuous record. Effective predictions can be made from observations through January. The predictors are the pre-season rainfall in the Nordeste itself, indices of the fields of the meridional wind component and of SST in the tropical Atlantic, and less importantly, an index of equatorial Pacific SST. This information serves as input to SMR, LDA, and neural networking. An approach by the UK Meteorological Office has as input information SST in the tropical Atlantic and equatorial Pacific. The diagnostic research at the University of Wisconsin also served as basis for numerical modeling experiments by other groups. [Figure 4](#) illustrates the performance of a model using SMR. [Figure 5](#) presents a comparison of performance by

Figure 4 Prediction of an index of March–June rainfall in northern Northeast Brazil from stepwise multiple regression, using as predictors October–January Nordeste rainfall (ONDJ), index of January meridional wind component over the tropical Atlantic (V), index of January SST field in the tropical Atlantic (ST29), and SST anomaly in equatorial Pacific (PAC). Solid dots denote regressed values for years up to 1957 and forecast values from 1958 onward, as separated by the vertical broken line. Open circles indicate observed MAMJ values.

(a) empirical prediction and (b) numerical modeling over the 32 year common period 1968–1999. Verification of forecast performance shows for the numerical modeling larger errors and it captures 30% of the variance as compared to the 59% by the empirical method.

North Atlantic Storms

Since the mid-1980s, seasonal forecasts have been issued for North Atlantic hurricane activity with remarkable success. Input information includes the stratospheric zonal wind component, El Niño developments in the Pacific, pressure over the Caribbean, and rainfall over West Africa.

El Niño and Southern Oscillation

Following the considerable understanding of the underlying atmospheric–hydrospheric mechanism offered by extensive empirical–diagnostic investigations, El Niño has been an early target of efforts in extended-range forecasting. It was the prediction of El Niño to which numerical modeling was first applied. Methods developed from a numerical ocean model driven by recently observed surface winds, to a coupled ocean–atmosphere model using the observed history of the Pacific wind field during the preceding years, to a two-tiered approach in which a model for predicting tropical Pacific SST is used in tandem with an atmospheric GCM. It may be anticipated that even though the upper-air flow patterns seem realistically depicted, the prediction of regional rainfall anomalies remains a challenge.

Figure 5 Time series plots of March–June precipitation indices in millimeters. (a) Empirical prediction E* dots, and gridded observations O* open circles; (b) predictions from numerical modeling M dots, with vertical line in lower left indicating correction for negative bias, and gridded observations O* open circles.

Purely statistical techniques have also proven effective for the prediction of El Niño, including CCA of SST and wind fields, SSA of the Tahiti minus Darwin index, and linear inverse modeling of SST.

To the extent that warm water anomalies in extended areas of the equatorial Pacific feed back into the atmospheric circulation, the prediction of El Niño is of interest beyond the Pacific domain proper. It must be noted, however, that the SO contributes substantially to the interannual climate variability only in limited regions of the tropics. With a view to implications for the global atmospheric circulation, at the Climate Prediction Center of NOAA observed surface and subsurface thermal conditions are input to an ocean model and an anomaly-coupling scheme is used for interaction with the atmospheric model. The Pacific El Niño phenomenon is clearly related to the SO, and this is commonly described by the Tahiti minus Darwin pressure index. Signals of the SO are pervasive, but only in limited domains of the tropics does this contribute substantially to the regional climate variability.

Australia

Lying as it does near a dipole of the SO, it is not surprising that the greater Australian region has its climatic variability strongly tied to the phases of this large-scale pressure seesaw. In the high SO phase, surface waters to the north of Australia and in the Indonesian seas tend to be anomalously warm, with low pressure and relatively abundant rainfall. In accordance with the prevailing SST anomalies, tropical storm activity also tends to be enhanced. Such processes in the large-scale circulation setting are being used to advantage for real-time forecasting of rainfall, tropical cyclone activity, and crop yields.

North America

Seasonal forecasts of the spatial patterns of temperature and precipitation anomalies over the United States are regularly issued by the Climate Prediction Center of NOAA, based on statistical methods and numerical modeling. The forecast system consists of tools that forecast the tropical Pacific SST and tools that forecast the US surface temperature and precipitation. Forecasts of tropical Pacific SST are produced from CCA of patterns of global sea level pressure and tropical Pacific SST, and from coupled ocean–atmosphere models run with full coupling in the tropical Pacific region. These statistical and numerical modeling results are then combined into a forecast of tropical Pacific SST. This along with the SST values observed elsewhere in the global ocean serve as boundary conditions to force an atmospheric GCM. Note that this two-tiered numerical modeling system is in principle applicable anywhere over the globe, depending on any skill that could be derived from it, but it is used operationally only for US seasonal forecasts. In addition to this two-tiered numerical modeling system, statistical techniques are also applied, namely optimal climate normals for the region and CCA of the global SST, northern hemispheric 700 hPa patterns, and US temperature and precipitation. A statistical consolidation

of the diverse tools is made to aid the forecasters in objectively combining the information. In the course of the annual cycle, skill is highest at the end of winter and summer, and poorest in between. In this context, lead times are less relevant, so forecasts are issued for the coming year; at certain seasons, skill is low even with the shortest lead times; and, at other seasons, whatever little is known is known well in advance. In a similar vein, experiences with India and Northeast Brazil have shown predictability a couple of months ahead of the season, with no improvement at shorter lead times.

Europe

Attempts at seasonal forecasting of temperature and precipitation by the UK Meteorological Office continue, based on statistical methods and numerical modeling. Wintertime SST anomalies in the North Atlantic serve as inputs to linear regression to predict summer temperature for central England. An extension of this work is devoted to the prediction of summer temperature over Europe. Associations with ENSO are found to be weak.

A major collaborative European effort involving 11 institutions in six countries, Prediction of Climate Variations on Seasonal to Interannual Time-Scales (PROVOST), aims at exploring the potential of numerical modeling for seasonal forecasting for the continent. Tentative results have been reported from the contribution of the UK Meteorological Office. ENSO has not furnished skill for the prediction of the winter or spring conditions. Interest also focuses on the possibility of predicting when a forecast will be skillful. Work continues.

Caveats

It is tempting to believe that the tropical climate prediction problem can be reduced to ENSO and that numerical modeling is the obviously superior tool in the long run. These widely held beliefs are briefly addressed in this section.

Regarding ENSO, it should be realized that interannual variability in the regional climate is directly due to anomalous behavior of the quasipermanent circulation systems in the region; to the extent that the SO is associated with variability in the regional circulation, it may show a correlation with regional climatic conditions. [Figure 6](#) offers some illustrations pertaining merely to diagnostics rather than prognosis. Thus, the October–November rains at the coast of equatorial East Africa are correlated at better than 0.8 with the concurrent surface westerlies over the equatorial Indian Ocean, as compared to correlations of only about 0.6 between the SO and the rains or winds. In a similar vein, the summer rainfall in the West African Sahel has correlations of around 0.6 with indices of the circulation but of only 0.3 with the SO. The rains of Brazil's Nordeste are correlated at about 0.7 with the regional circulation, whereas the SO has correlations of only about 0.3 with either the rain or the circulation.

The development of both empirical and numerical modeling methods for operational climate prediction has been pioneered by two large governmental institutions: the Hadley Center of the UK Meteorological Office and the Climate Prediction Center of

Figure 6 Schemes of long-term mean diagnostic relationships, showing coefficients of concurrent correlation between indices of the Southern Oscillation (SO), the regional circulation (CIRC), and rainfall at the coast of eastern Africa (October–November), in the West African Sahel (July–August), and in Brazil’s Nordeste (March–April).

NOAA. A group from the latter institution has critically examined the potential of the two approaches in review papers half a decade apart. In the earlier review, they found that the two approaches delivered roughly equally skillful forecasts. Five years later, they confirmed this assessment and speculated about the possibility that the numerical models will never be able to outperform empirical models. Such perception is shared by other authors in later publications. Concerning expectations from downscaling in numerical modeling appreciation is in order for precision versus accuracy, an issue meriting further exploration.

In this context, Nicholls’s cautioning in 1999 against cognitive illusions in climate prediction is pertinent. With reference to a recent experience, he noted: “The general view among scientists of the accuracy of forecasts of the El Niño of 1997 appears to illustrate hindsight bias. None of the climate forecast systems predicted anything more than slight warming. Yet the forecasting of the 1997 El Niño with large models is now regarded as a stunning success. Some of the model predictions for the 1997/98 event were very poor. It seems these misfortunes are being ignored when the stunning success of the El Niño model forecasts is assessed. People seek confirmatory evidence and avoid the search for disconfirming evidence”.

Outlook

There has been encouraging progress in the seasonal prediction of interannual climate variability. While forecasting methods are being developed for ever more target regions, the impression remains that climate anomalies may be highly predictable for only limited areas of the tropics where the bulk of the

rainfall is prevalingly derived from a single well-organized quasipermanent circulation system (such as the ITCZ), especially at the extremes of the planetary-scale annual cycle. Fortunately, however, these regions tend naturally to coincide with areas that are most prone to climatic anomalies and where the human impact is most severe. For other vast domains, the prospects of seasonal prediction may be more remote. The extent to which moderate intrinsic predictability may be practically useful in agricultural and economic planning is an issue that remains to be explored in continuing discourse between the forecasting community and the potential user community. In this context, climate monitoring should be cultivated in tandem with climate prediction.

It seems desirable to pursue in parallel the general circulation-based empirical approach and the numerical modeling, because this combination should be mutually fruitful and offer insight into the atmosphere–ocean mechanisms involved. It should be realized that, although the Southern Oscillation signal is pervasive, climate anomalies in many regions are not prevalingly related to the SO. Decadal-scale changes in predictability are poorly understood and are an impediment to prediction regardless of technique. A broad-based effort is needed, combining empirical and modeling approaches and coupling diagnostics with prognosis. Documentation of the method, verification of performance on an independent data set, and evaluation of real-time forecasts are always imperative.

Introduction

In the final decade of the twentieth century, recovery of high-resolution paleoclimate records of natural climate variability (see **Paleoclimatology**: Ice Cores; Varves) improved dramatically our perception of the long-term behavior of the Earth's climate. Immediately apparent from these records was the fact that the once implicit notion that the modern-day climate system (following termination of the last ice age) was relatively stable, was no longer tenable. This notion quickly yielded to one in which the Earth's climate is continually changing over all time scales. Presumably it will continue to change, with or without human-induced (anthropogenic) influences.

Climate, as measured by the averaged value of any characteristic of weather, such as temperature or precipitation, can show considerable differences in how it varies through time and across the globe. For example, it might undergo a smooth or abrupt transition from one quasi-stable state to another; it may vary cyclically, not unlike the familiar daily or annual cycles, but with cycles lasting tens or hundreds of years or longer; and it may vary through changes in extreme states (e.g., colder winters), or in the magnitude or degree of fluctuations (e.g., more storms, or larger differences from one year to the next). When such variations occur over, or persist for, tens to hundreds of years, we classify them as decadal-to-centennial variability. For convenience, variability over these time scales is referred to as 'dec-cen' climate variability.

From a practical standpoint, dec-cen climate variability involves climate change that occurs once in a while over the course of a human lifetime (e.g., the 'real' winters your grandfather remembers), or in general it occurs slowly relative to our year-to-year experience of climate. This is distinctly different from shorter-term change that occurs rapidly, and often apparently dramatically within a year or several years (see **Climate and Climate Change**: Climate Variability: Seasonal and Interannual Variability). The difference extends well beyond our perception of the change. It also has considerable implications regarding how the change or variations influence society and how we study them.

Dec-Cen Variability and Society

From a societal perspective, the time scale over which climate variability manifests itself is important from several perspectives. Short-term variability, such as that related to El Niño events (see **Tropical Meteorology and Climate**: El Niño and the Southern Oscillation: Observation; El Niño and the Southern Oscillation: Theory), influences everything from agriculture to recreation. But if such short-term change persists for dec-cen time scales, the implications are considerably different. For example, in the 1990s the Midwestern United States was twice hit with devastating floods (1993 and 1997). As rare and

extreme short-term climate events, society must deal with their impact through disaster relief and flexible adaptive measures. But if they are a consequence of changed climate conditions during the latter part of the twentieth century and represent a regular characteristic of the new climate state, then such flooding must be dealt with through policy decisions and investments in infrastructure.

The latter requires considerable foresight and the best possible information. This is particularly important for dec-cen variability since the magnitude of climate change is often proportional to the length of time over which it operates. Changes on dec-cen time scales can involve potential shifts in agriculture belts, in drought/flooding frequency, magnitude and extent, significant rises in sea level, fundamental adjustments in energy usage, etc. It can also modify the larger background climate state that influences our ability to predict shorter-term climate events, such as El Niño. An ability to recognize or anticipate such change in order to minimize the negative impacts and optimize the positive ones often requires advance action and decisions. Consequently, an ability to forecast such change, recognize its signs, or understand its potential is a fundamental goal of modern climate studies.

Unfortunately, the potentially huge impacts (positive and negative) of dec-cen variations are typically, though not always, realized only slowly with time. Such slow, often imperceptible, change disguises the potential long-term implications of the change, while tending to undermine the immediacy of the problem and our resolve to address it. So too does the knowledge that any experienced change may be part of a longer cycle that will be returning to its previous (acceptable) state in due time. Regardless, climate will change and infrastructure/policy decisions will ultimately be made either in response to the change or in anticipation based on imperfect information. Thus, understanding dec-cen climate change in order to provide sound information regarding the potential or likelihood of change is fundamental to our long-term, social and individual, well-being.

The Study of Dec-Cen Variability

The study of dec-cen climate variability is new, and is at a distinct disadvantage relative to that of shorter-term climate variability. In fact, the differences are significant enough that the paradigm by which climate studies, particularly prediction, have heretofore relied on must be changed to study dec-cen climate variability. Because dec-cen variability involves slow change, long data records are required for model calibrations, predictive skills (the ultimate test of understanding), and observational analyses. That is, records must contain enough occurrences (realizations) of the phenomena being examined to give a reasonable

statistical foundation for analysis or model–data comparison. For dec–cen variability, only the bare minimum of such data sets currently exist.

It will take decades into the future to obtain long and comprehensive enough modern records for dec–cen studies. The historical record from modern instruments does not extend far enough back in time and is typically too sparse in most locations. Invaluable advances are being made in our ability to interpolate these historical data into an internally and dynamically consistent, comprehensive ‘reanalysis’ data set through the use of models. The paleoclimate records, our greatest hope, are still limited in their spatial distribution, and sometimes accuracy and precision, though they are improving rapidly (*see Paleoclimatology: Ice Cores; Varves*).

Contrast this to the remarkably successful paradigm used to advance short-term climate prediction. In that case, numerical models or statistical methods for prediction can be immediately calibrated against the past few decades of observations. They can then be tested against an upcoming year, and soon thereafter modified according to their success or failure. This allows a very effective and rapid advancement in short-term prediction.

For prediction of dec–cen climate variability, this paradigm is clearly impractical except for cases where the change is realized at a fast enough rate to allow some testing in the near distant future (this is the paradigm being used to predict greenhouse warming; *see Global Change: Biospheric Impacts and Feedbacks; Climate Record: Surface Temperature Trends; Upper Atmospheric Change. Ozone Depletion and Related Topics: Long Term Ozone Changes*). Consequently, we are forced into a different paradigm, dependent upon the collection of comprehensive and widespread paleoclimate data sets and the new model reanalysis products. We are equally dependent upon sustained acquisition of observations that will eventually provide that comprehensive data set necessary for quick hindcast calibration and evaluation of models for future generations.

Furthermore, because dec–cen variability involves such long time scales, its study is faced with a number of additional difficulties: (1) Even the relatively high-order physics, those that describe and control processes that do not impose any significant influence over short time scales, have enough time to introduce systematic biases or feedbacks into the system which must be accounted for over long time scales. In models, it is typically necessary that all of the physics of a given order (i.e., relative level of importance) be included since they often work to mitigate or enhance the influence of one another. (2) With longer time scales, changes can be communicated over farther spatial distances and have time to interact with different components of the climate system. For example, predictions of El Niño have been quite successful without taking into consideration the current state of the polar sea ice fields, the level of atmospheric CO₂, or the state of vegetation on land. However, if one wishes to predict how the frequency, intensity, or other characteristics of El Niños may vary over decade-to-century time scales, it is possible that any and all of these may impart some influence that ultimately impacts the tropical Pacific and its evolution.

The implications of these are tremendous. Numerical models examining dec–cen climate variability must therefore include some treatment of detailed physical processes not required in shorter-term climate models. These detailed processes typically operate on the smallest spatial scales, and may have their largest influence in regions quite remote from the region of interest (for example, some aspects of the ocean circulation originate in the subpolar regions as a result of small-scale local interactions, and from there transport heat and salt to the remainder of the world’s oceans). This requires that the models either break the Earth into a great many very small grid cells (*see Numerical Models: Methods*), or include parameterizations of how larger areas may respond in average to the small (‘subgrid’) scale processes that cannot be explicitly resolved. The former allows for better treatment of the physics but at tremendous computational burden (making a computer simulation of the model extremely slow and expensive); the latter relieves some of the computational burden but at the cost of possibly overlooking some of the additional details that may be important. In addition to these detailed processes, the models must contain other parts of the climate system not required in the short-term climate models, such as the biosphere, cryosphere, and atmospheric composition, or more aspects of the ocean, such as the very slow deep ocean circulation. Not only do the additional physics, global scale, and finer model resolution add computational burden, but the very nature of the problem being decade-to-century time scale variability requires that such burdened models run for inordinately long simulation periods as well. Consequently, model simulations are slow, many of the physics missing or uncertain, and the models are so complex that relatively few exist. This limits our ability to assess dec–cen climate variability by multiple experiments under a variety of conditions with many different models involving different parameterizations (though this is still done to the extent possible, but it is greatly hindered by these extreme demands).

Finally, the dec–cen problem is also faced with making predictions based on changes in greenhouse gases (the composition of the atmosphere) that are a function of highly uncertain future emission scenarios. Therefore, even if we succeed in understanding natural dec–cen climate variability, future predictions must be compromised by including uncertain estimates of how the atmospheric composition will change. Here we are forced to depend on multiple forecasts using a variety of different emission scenarios, but again the large computational burden of such comprehensive models limits the practical number of experiments that can be run and examined. Note that it is sometimes taken for granted that the expression climate ‘change’ represents variations in climate due to anthropogenic reasons, where climate ‘variability’ refers to natural variability. In this article, both change and variability are used interchangeably, with the differentiation between natural and anthropogenic change explicitly stated when required.

Modes of Dec–Cen Variability

Climate variability on decade-to-century time scales has manifested itself in historic times through a number of fairly

well-known climate events (see the [Further Reading](#) section). Some of the more notable ones include the prolonged drought of the Great Plains of the United States responsible for the dust bowl of the 1930s, and the crippling drought of the Sahel in northern Africa during the latter decades of the twentieth century, which killed over half a million people in the mid-1970s. The global warming of the twentieth century or the enhanced warming started in the mid-1970s. Changes in the Earth's ozone layer have led to increases in the level of ultra-violet radiation at the Earth's surface in high southern and, more recently, northern latitudes. Dec-cen changes in cloud cover also have led to increased surface radiation in Australia, North America, India, and Europe throughout the twentieth century. The number of major hurricanes varies on dec-cen time scales, as do the number of Nor' Easters ravaging the north-east coast of North America. Sea level has been rising throughout the last century (~ 20 cm) and changes in ecosystems directly related to dec-cen climate have been dramatic in fisheries: the North Atlantic cod and eastern North Pacific salmon. Paleoclimate evidence suggests that dec-cen climate variability is also responsible for the fall of civilizations (e.g., the Classic Maya) and mass migrations of societies (e.g., the Nordestinos of Brazil).

While the dramatic nature of these events makes them rather conspicuous examples of dec-cen variability, much of our focus is directed toward a broader view of dec-cen variability. Specifically, observations made during the last several decades suggest that climate variability over large expanses of the Earth seems to organize itself into patterns that preserve a general shape in space, but whose amplitude may change in time. Such coherent structure is referred to as a mode of variability or, to admit a slightly broader class of structures, they are more generally referred to as climate patterns or spatial-temporal patterns.

Our study of such patterns is relatively new and, because of the lack of historical global data (though, here reanalysis data have proven invaluable), we do not have a comprehensive inventory of the global patterns, nor do we understand their mechanisms, couplings, longevity, or full implications for climate prediction. However, we are encouraged by the study of the most thoroughly investigated pattern: the El Niño Southern Oscillation (ENSO) pattern. El Niño and La Niña are extreme states of the ENSO pattern (see **Tropical Meteorology and Climate: Monsoon: ENSO–Monsoon Interactions**). The ENSO phenomenon is characterized by a pattern of tropical Pacific sea surface temperature (SST) relative to the mean SST. Studies of it revealed that the state of the pattern (e.g., periods when the eastern tropical Pacific SST was abnormally high) was related to regional climate in various regions around the world. Further investigation revealed that the pattern was predictable according to some simple laws involving the interaction of the atmosphere and ocean (over short time scales). This led to considerable insights regarding the nature of climate, the coupling between climate components (in this case, the ocean and atmosphere), scales of influence and, most importantly, our first successful climate predictions (over seasonal to interannual time scales). We are hopeful that additional predictions for other regions of the Earth may be realized in analogous fashion for dec-cen varying patterns.

These other patterns are not as well documented or studied, but indeed they do appear to be related to regional climate. Some are also related to the frequency of hurricanes, Nor' Easters, crop yields, and fisheries. The covariation of two patterns dominated global temperature variations since the mid-1970s. Others display regional or global teleconnections, and they may serve to focus different climate forcings and processes into single coherent responses. Because of these attributes and covarying relationships, it is hoped that their further study may ultimately yield benefits similar to those obtained through the study of ENSO. Patterns also provide an obvious means for breaking the complex climate system down into a finite set of manageable, and hopefully predictable, components.

Most modes are defined by statistical classifications of the observed variability in surface temperature, sea-level pressure, or other quantities. The precise definition may vary according to the statistical methodology employed to define them (see **Statistical Methods: Data Analysis: Empirical Orthogonal Functions and Singular Vectors**). Statistical patterns may ultimately prove to be related to physical laws or to the distribution of land and ocean, of mountains, etc. They may also be artifacts of nature, whereby they are not stable over long periods of time, or they may be statistical artifacts.

The two most important patterns that show dec-cen variability are the North Atlantic Oscillation (NAO; see **Climate and Climate Change: Climate Variability: Seasonal and Interannual Variability**) and the Pacific–North American Teleconnection (PNA; 0400). In addition to these, there is a pattern in the tropical Atlantic (referred to as tropical Atlantic SST variability), in which SST often shows anomalous warmth (referred to as a 'warm pool') in the tropical North Atlantic and a complementary cool pool in the tropical South Atlantic, or vice versa. These seem to vary coherently over decadal time scales, though they vary independently on shorter time scales in these regions. These low-frequency SST phenomena show concurrent anomalies in the rainfall over Brazil and northern Africa. It has also been suggested that the decadal changes in the SST in the subtropical North Atlantic may be responsible for changes in the distribution and intensity of hurricanes in that region.

Likewise there is a decadal ENSO-like pattern, where low-frequency covarying changes in the tropical Pacific atmosphere and ocean strongly resemble the pattern of the interannual ENSO phenomenon, including teleconnected anomalies in the midlatitude atmosphere and ocean of the North Pacific. These decadal ENSO-like anomalies are also teleconnected throughout the tropics, with large concurrent changes in tropical Atlantic and Indian Ocean SST, in addition to the North Pacific.

This anomaly pattern has shown an extended 'warm' phase throughout the last few decades of the twentieth century, which preceded a significant reduction in the alpine glaciers throughout the tropics. The frequency of precipitation, stream flow, and snowpack in the north-west and south-west of North America are also well correlated with this time series describing the decadal ENSO-like climate phenomenon variability.

A number of regional atmospheric patterns have been analyzed such as the North Pacific Oscillation (NPO), West

Pacific Oscillation (WPO), West Atlantic Pattern, and Pacific Decadal Oscillation (PDO). It is not clear how these are related to the PNA or each other (if at all). A completely different kind of pattern, involving sea ice, has been found in the Southern Ocean, and is called the Antarctic Circumpolar Wave (ACW). This pattern is characterized by deviations in the Antarctic sea ice extent from monthly climatological averages, though it is also apparent in surface wind, SST, and sea-level pressure anomalies near the winter ice edge. It is also highly coherent with temporal variations in ENSO and the Indian Ocean monsoons. Other atmospheric patterns have been identified in the Southern Hemisphere, though the data are typically too sparse in time and space to allow more detailed analyses of these.

In addition to the above, there are structures which may, or may not, be considered climate patterns, though they are often related to the other patterns or presented in a similar manner. For example, the Asian monsoon, though predominantly a seasonal signal, is strongly correlated to ENSO and shows decadal variability as indexed by precipitation and wind speeds over India. The global thermohaline circulation (*see Oceanographic Topics: Thermohaline Circulation*) has been tied to distinct changes in the ocean surface conditions and NAO in the North Atlantic Ocean.

Mechanisms of Dec-Cen Variability

The mechanisms responsible for dec-cen climate variability are conveniently separated into those that arise as a consequence of changes in the external forcing of the system and those that arise due to internal variability within the system (independent of changes in the forcing). The external forcing on the Earth's climate consists of solar radiation impinging on the Earth's atmosphere, aerosols (particles or liquid suspended in air) from volcanic eruptions, and the chemical composition of the atmosphere (controlled by natural and anthropogenic sources/sinks of greenhouse gases). The ice ages and the more recent Little Ice Age have been attributed to changes in the intensity of incoming solar radiation. Such changes are typically very small (of the order of a couple percent for the ice age changes associated with changes in the Earth's orbital geometry; and even smaller for the Little Ice Age associated with changes in sunspot activity). Unfortunately, while the observed climate variations of the ice ages and Little Ice Age are consistent with the variations in solar activity, we still do not understand how such minuscule changes can drive such significant responses.

Clearly changes in climate associated with changes in the external forcing require that we can predict the changes in the forcing. Therefore, climate predictions and mechanisms of change associated with changes in external forcing require studies that work under given scenarios of change.

The most fundamental theory regarding internal dec-cen climate variability (i.e., independent of changes in external forcing) was presented in an elegant theory by Hasselmann, whereby the day-to-day weather, representing high-frequency climatic noise, works to drive a slow component of the climate system such as the ocean. Relative to the atmosphere, the ocean has an enormous heat capacity and mixes slowly. These characteristics regulate the speed with which it can

respond to changes in the forcing (thus, it is considered a slow component relative to the atmosphere which is a fast component). The 'muted' response of the ocean serves to integrate the high-frequency atmospheric forcing resulting in an ocean that also varies but over considerably slower time scales. This theory, in combination with the influence of land-sea contrasts and distribution of mountain belts, allows for spatially varying patterns of dec-cen variability. It represents the most basic mechanism of dec-cen variability (effectively, our 'null hypothesis' in the absence of more complex mechanisms).

Other possible internal mechanisms include the interactions between the slow variations of the slow components (e.g., the ocean and the cryosphere), and the coupling of system components that individually may not show slow variability, but together can. A considerable amount of attention has been given to mechanisms of decadal ENSO variability whereby tropical SST anomalies are quickly propagated through the atmosphere to the extratropics and midlatitudes where they introduce local anomalies to the ocean. The ocean retains the anomaly while slowly transporting it back to the tropics (via surface currents, subsurface currents, etc.) where it moderates the tropical SST causing further anomalies and continuation of the cycle. Considerable progress has been made toward identifying potential mechanisms, though more work is still required. Presently, these hypotheses help to focus model experiments and observational studies.

Future Directions and Needs

As stated, the study of decadal-to-centennial climate variability is in its infancy. New discoveries are being made each year, and at the time of this writing we are clearly on the steep slope of the learning curve. The task is onerous given the considerable demands on the models for including all components of the climate system (atmosphere, ocean, cryosphere, biosphere, and land surface), resolving processes operating at the smallest spatial scales to the largest, and having to integrate (run) the models for decades to centuries of model years to realize a single simulation. More powerful computers and their broader availability to climate researchers will aid considerably in this respect, as will close collaboration between scientists of multiple disciplines, and between observationalists, theorists and modelers.

We are faced with changing atmospheric concentrations of radiatively active gases and we need to obtain more accurate records of the actual emission rates to help constrain models simulating past conditions. We have limited observations of dec-cen climate variability, and those from the twentieth century may already be contaminated by anthropogenic climate change (masking the signal of natural variability that is required in order to ultimately recognize an anthropogenic change from the natural variability background). There are additional demands on the data quality required to efficiently study dec-cen variability. This reflects the fact that dec-cen change proceeds at such a small pace on a year-to-year basis, and that any such change is easily lost within the diurnal and seasonal cycle as well as standard interannual variability, all of which are large relative to the annual dec-cen change. Thus, we need

high-precision instruments to pick up dec-cen change as early as possible.

At present, there is no long-term climate observing system for dec-cen variability in place. Consequently, if we are to provide an observational basis from which future generations will be able to more reliably diagnose their model (hindcast) predictions, and analyze comprehensive records of dec-cen variability, we must begin a systematic collection of key variables now. This requires close coordination between research and operational groups.

Despite these impediments, we are encouraged by the fact that climate patterns may ultimately allow us to predict some aspects of dec-cen climate variability. The problem is of considerable importance and will yield invaluable insights regarding the nature and sensitivities of our planet's climate system.

Climate Variability: Nonlinear and Random Effects

M Ghil, Ecole Normale Supérieure, Paris, France; and University of California, Los Angeles, CA, USA

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

Nonlinear and random effects are pervasive in the atmospheric, oceanic, and climate sciences. This article gives a unified treatment of such effects from the point of view of the theory of dynamical systems and their bifurcations. Energy balance models are used to illustrate multiple equilibria, while multidecadal oscillations in the thermohaline circulation illustrate the transition from steady states to periodic behavior. Random effects are introduced in the setting of random dynamical systems, which permit a unified treatment of both nonlinearity and stochasticity. This treatment is applied to a stochastically perturbed version of the classical Lorenz convection model.

Introduction

The global climate system is composed of a number of subsystems—atmosphere, biosphere, cryosphere, hydrosphere, and lithosphere—each of which has distinct characteristic times, from days and weeks to centuries and millennia. Each subsystem, moreover, has its own internal variability, all other things being constant, over a fairly broad range of timescales. These ranges overlap between one subsystem and another. The interactions between the subsystems thus give rise to climate variability on all timescales.

We outline here the rudiments of the way in which *dynamical systems theory* is starting to provide an understanding of this vast range of variability. Such an understanding proceeds through the study of successively more complex patterns of behavior. These spatiotemporal patterns are studied within narrower ranges of timescales, such as *intraseasonal*, *interannual*, *interdecadal*, and *multimillennial*; each of these frequency bands is covered in a separate article of this Encyclopedia. The main results of dynamical systems theory that have demonstrated their importance for the study of climate variability involve *bifurcation theory* and the *ergodic theory* of dynamical systems. Since the first edition of this encyclopedia, the theory of *random dynamical systems* has made substantial contributions as well, and these are now accounted for here, too.

In the next section, we describe the climate system's overall balance between incoming solar radiation, dominated by shortwaves, and outgoing terrestrial radiation, dominated by long waves. This balance is consistent with the existence of *multiple equilibria* of surface temperatures. Such multiple equilibria are also present for other balances of climatic actions and reactions. Thus, on the intraseasonal timescale, the thermal driving of the midlatitude westerly winds is countered by surface friction and mountain drag. Multiple equilibria typically arise from *saddle-node bifurcations* of the governing equations. Transitions from one equilibrium to another may result from small and random pushes, a typical case of minute causes having large effects in the long term.

In the following section, we sketch the ocean's overturning circulation between cold regions, where water is heavier and sinks, and warm regions, where it is lighter and rises. The effect of temperature on the water masses' density and, hence, motion is in competition with the effect of salinity: density increases, through evaporation and brine formation, compete

further with decreases in salinity and, hence, density through precipitation and river runoff. These competing effects can also give rise to two distinct equilibria.

In the present-day oceans, a *thermohaline* circulation (THC) prevails, in which the temperature effects dominate. In the remote past, about 50 My ago, a *halothermal* circulation may have obtained, with salinity effects dominating. In a simplified mathematical setting, these two equilibria arise by a *pitchfork bifurcation* that breaks the problem's mirror symmetry about the equator. On shorter timescales, of decades-to-millennia, *oscillations* of intensity and spatial pattern in the THC seem to be the dominant mode of variability. We show how interdecadal oscillations in the ocean's circulation arise by *Hopf bifurcation*.

In the final section, we address the way that faster processes, modeled as random effects, can interact with the slower, nonlinear ones. The combined treatment of the nonlinear and stochastic processes can reveal amazingly fine structure in the climate system's behavior, but also—and rather surprisingly—add robustness and predictability to the results. Concluding remarks follow.

Energy Balance Models (EBMs) and the Modeling Hierarchy

The methods of dynamical systems theory have been applied first to simple models of atmospheric and oceanic flows, starting anithybout 50 years ago. More powerful computers now allow their application to fairly realistic and detailed models of the atmosphere, ocean, and the coupled atmosphere–ocean system. The present section starts, therefore, by presenting such a hierarchy of models.

This presentation is interwoven with that of the *successive bifurcations* that lead from simple to more complex solution behavior for each climate model. Useful tools for comparing model behavior across the hierarchy and with observations are provided by ergodic theory. Among these, advanced methods for the analysis and prediction of uni- and multivariate time series play an important role.

Radiation Balance and EBMs

At present, the most highly developed hierarchy is for atmospheric models. Atmospheric models were originally

developed for weather simulation and prediction on the timescale of hours to days. Currently, they serve—in a stand-alone mode or coupled to oceanic and other models—to address climate variability on all timescales.

The first rung of the modeling hierarchy for the atmosphere is formed by zero-dimensional (0D) models, where the number of dimensions, from zero to three, refers to the number of independent space variables used to describe the model domain, i.e., to physical space dimensions. Such 0D models essentially attempt to follow the evolution of global surface air temperature $\bar{T}$ as a result of changes in global radiative balance:

$$c \frac{d\bar{T}}{dt} = R_i - R_o \quad [1a]$$

$$R_i = \mu Q_o \{1 - \alpha(\bar{T})\}, \quad R_o = \sigma m(\bar{T}) \bar{T}^4 \quad [1b, c]$$

Here R_i and R_o are, respectively, incoming solar radiation and outgoing terrestrial radiation. The heat capacity c is that of the global atmosphere, plus that of the global ocean or some fraction thereof, depending on the timescale of interest: one might only include in c the ocean mixed layer when interested in subannual timescales but the entire ocean when studying paleoclimate. The rate of change of $\bar{T}$ with time t is given by $d\bar{T}/dt$, while Q_o is the solar radiation received at the top of the atmosphere, s is the Stefan–Boltzmann constant, and m is an insolation parameter, equal to unity for present-day conditions. To have a closed, self-consistent model, the planetary reflectivity or albedo α and grayness factor m have to be expressed as functions of $\bar{T}$; $m = 1$ for a perfectly black body and $0 < m < 1$ for a gray body like planet Earth.

There are two kinds of one-dimensional (1D) atmospheric models, for which the single spatial variable is latitude or height, respectively. The former are so-called EBM, which consider the generalization of the model eqn [1] for the evolution of surface–air temperature $T = T(x, t)$, say,

$$c(x) \frac{\partial T}{\partial t} = R_i - R_o + D \quad [2]$$

Here the terms on the right-hand side can be functions of the meridional coordinate x (latitude, colatitude, or sine of latitude), as well as of time t and temperature T . The horizontal heat flux term D expresses heat exchange between latitude belts; it typically contains first and second partial derivatives of T with respect to x . Hence, the rate of change of local temperature T with respect to time also becomes a partial derivative, $\partial T/\partial t$.

The first striking results of theoretical climate dynamics were obtained in showing that eqn [2] could have two stable steady-state solutions, depending on the value of the insolation parameter μ , cf. eqn [1b]. This multiplicity of stable steady-states, or physically possible ‘climates’ of our planet, can be explained, in its simplest form, in the 0D model eqns. [1a]–[1c].

The simple explanation resides in the fact that—for a fairly broad range of μ values around $\mu = 1.0$ —the curves for R_i and R_o as a function of $\bar{T}$ intersect in three points. One of these corresponds to the present climate (highest $\bar{T}$ value), and another one to an ice-covered planet (lowest $\bar{T}$ value); both of these are stable, while the third one (intermediate $\bar{T}$ value) is unstable. To obtain this result, it suffices to make two assumptions: (1) $\alpha = \alpha(\bar{T})$ is a piecewise linear function of $\bar{T}$, with high albedo at low temperature, due to the presence of

snow and ice, and low albedo at high $\bar{T}$, due to their absence; and (2) $m = m(\bar{T})$ is a smooth, increasing function of $\bar{T}$ that attempts to capture in its simplest form the ‘greenhouse effect’ of trace gases and water vapor.

The *bifurcation diagram* of such a 1D EBM is shown in Figure 1. It displays the model’s mean temperature as a function of the fractional change μ in the insolation $Q = Q(x)$ at the top of the atmosphere. The ‘S’-shaped curve in the figure arises from two back-to-back saddle-node bifurcations. The *normal form* of the first one is

$$\dot{X} = \mu - X^2 \quad [3]$$

Here X stands for a suitably normalized form of $\bar{T}$ and $\dot{X} \equiv dX/dt$ is the rate of change of X , while μ is a parameter that measures the stress on the system, in particular a normalized form of the insolation parameter.

The uppermost branch corresponds to the steady-state solution $X = +\mu^{1/2}$ of eqn [3] and is stable. It matches rather well Earth’s present-day climate for $\mu = 1.0$, more precisely the steady-state solution $T = T(x; \mu)$ of the full 1D EBM (not shown) matches closely the annual mean temperature profile from instrumental data over the last century.

Figure 1 Bifurcation diagram for the solutions of an EBM, showing the annual mean temperature $\bar{T}$ vs fractional change of insolation at the top of the atmosphere μ . The arrows pointing up and down at about $\mu = 1.4$ indicate the stability of the branches: toward a given branch if it is stable and away if it is unstable. The other arrows show the hysteresis cycle that global temperatures would have to undergo for transition from the upper stable branch to the lower one and back. The angle γ gives the measure of the present climate’s sensitivity to changes in insolation. Reproduced from Ghil, M., Childress, S., 1987. *Topics in Geophysical Fluid Dynamics: Atmospheric Dynamics, Dynamo Theory and Climate Dynamics*. New York, NY/Berlin: Springer-Verlag.

The intermediate branch starts out at the left, it corresponds to the second solution, $X = -\mu^{1/2}$, of eqn [3] and it is unstable. This unstable branch blends smoothly into the upper branch of a coordinate-shifted and mirror-reflected versions of eqn [3], say,

$$\dot{X} = \mu - \mu_0 + (X - X_0)^2, \quad \text{where } \mu_0 = 1 \text{ and } X_0 = -\frac{1}{2} \quad [4]$$

This branch, $X = X_0 + (\mu_0 - \mu)^{1/2}$, is also unstable. Finally, the lowermost branch in Figure 1 corresponds to the second steady-state solution of eqn [4], $X = X_0 - (\mu_0 - \mu)^{1/2}$, and it is also stable. This last branch represents an ice-covered planet at the same distance from the Sun as the Earth.

The fact that the upper-left bifurcation point (μ_c, T_c) in Figure 1 is so close to present-day insolation values created great concern in the climate dynamics community in the mid-1970s, when these results were obtained. Indeed, much more detailed computations (see below) confirmed that a reduction of about 2–5% of insolation values would suffice to precipitate the Earth into a ‘deep freeze’. The great distance of the lower-right bifurcation point (μ_d, T_d) from present-day insolation values, on the other hand, suggests that one would have to nearly double atmospheric opacity, say, for the Earth’s climate to jump back to more comfortable temperatures.

Other Atmospheric Processes and Models

The 1D atmospheric models in which the details of radiative equilibrium are investigated with respect to a height coordinate z (geometric height, pressure, etc.) are often called *radiative–convective models*. This name emphasizes the key role that convection plays in vertical heat transfer. While these models preceded historically EBMs as rungs on the modeling hierarchy, it was only recently shown that they, too, could exhibit multiple equilibria. The word (stable) ‘equilibrium’, here and in the rest of this article, refers simply to a (stable) steady state of the model, rather than to a true thermodynamic equilibrium.

Two-dimensional (2D) atmospheric models are also of two kinds, according to the third space coordinate that is not explicitly included. Models that resolve explicitly two horizontal coordinates, on the sphere or on a plane tangent to it, tend to emphasize the study of the dynamics of large-scale atmospheric motions. They often have a single layer or two. Those that resolve explicitly a meridional coordinate and height are essentially combinations of EBMs and radiative–convective models and emphasize therewith the thermodynamic state of the system, rather than its dynamics.

Yet another class of ‘horizontal’ 2D models is the extension of EBMs to resolve zonal, as well as meridional surface features, in particular land–sea contrasts. We shall see in the section on “Bifurcation diagrams for GCMs” how such a 2D EBM is used, when coupled to an oceanic model.

Schneider and Dickinson in 1974, as well as Ghil and Robertson in 2000 have discussed additional types of 1D and 2D atmospheric models. See [Further Reading](#) for references to these and to the types discussed above, along with some of their main applications. Finally, to encompass and resolve the main atmospheric phenomena with respect to all three spatial coordinates, *general circulation models* (GCMs) occupy the pinnacle of the modeling hierarchy.

The dependence of mean zonal temperature on the insolation parameter μ (the normalized ‘solar constant’)—as obtained for 1D EBMs and shown in Figure 1 here—was confirmed, to the extent possible, by using a simplified GCM, coupled to a ‘swamp’ ocean model. More precisely, forward integrations with a GCM cannot confirm the presence of the intermediate, unstable branch. Nor was it possible in the mid-1970s, when this numerical experiment was done, to reach the ‘deep-freeze’ stable branch, because of the GCM’s computational limitations. But the parabolic shape of the upper, present-day like branch near the upper-left bifurcation point in the figure, cf. eqn [3], was well supported by the GCM simulations.

Ghil and Robertson have also described the separate hierarchies that have grown over the last quarter century in modeling the ocean and the coupled ocean–atmosphere system. More recently, an overarching hierarchy of earth system models—that encompass all the subsystems of interest, atmosphere, biosphere, cryosphere, hydrosphere, and lithosphere—has been developing. Eventually, the partial results about each subsystem’s variability, outlined in this section and the next one, will have to be verified from one rung to the next of the earth system modeling hierarchy.

Interdecadal Oscillations in the Oceans’ THC

Theory and Simple Models

Historically, the THC was first among the climate system’s major processes to be studied using a very simple mathematical model. Stommel formulated in 1961 a two-box model and showed that it possessed multiple equilibria.

A sketch of the Atlantic Ocean’s THC and its interactions with the atmosphere and cryosphere on long timescales is shown in Figure 2. These interactions can lead to climate oscillations with multimillennial periods, such as the Heinrich events, and are summarized in the figure’s caption. An equally schematic view of the global THC is provided by the widely known ‘conveyor belt’ diagram. The latter diagram does not commonly include the THC’s interactions with water in both its gaseous and solid phases, which the former does include.

Basically, the THC is due to denser water sinking, lighter water rising, and water mass continuity closing the circuit through near-horizontal flow between the areas of rising and sinking. The effects of temperature and salinity on the ocean water’s density, $\rho = \rho(T, S)$, oppose each other: The density ρ decreases with increasing T and increases with increasing S . It is these two effects that give the THC its name, from the Greek words for T and S . In high latitudes, ρ increases as the water loses heat to the air above and, if sea ice is formed, as the water underneath is enriched in brine. In low latitudes, ρ increases due to evaporation but decreases due to sensible heat flux into the ocean.

For the present climate, the temperature effect is stronger than the salinity effect, and ocean water is observed to sink in certain areas of the high-latitude North Atlantic and Southern Ocean—with very few and limited areas of deepwater formation elsewhere—and to rise everywhere else. Thus, in a *thermohaline* regime, T is more important than and hence comes before S . During some remote geological times, deepwater may

Figure 2 Diagram of an Atlantic meridional cross section from North Pole (NP) to South Pole (SP), showing mechanisms likely to affect the THC on various timescales. Changes in the radiation balance $R_{\text{in}} - R_{\text{out}}$ are due, at least in part, to changes in extent of Northern Hemisphere (NH) snow and ice cover, V , and how they affect the global temperature, T ; the extent of Southern Hemisphere (SH) ice is assumed constant, to a first approximation. The change in hydrologic cycle expressed in the terms $P_{\text{rain}} - P_{\text{evap}}$ for the ocean and $P_{\text{snow}} - P_{\text{abl}}$ for the snow and ice is due to changes in ocean temperature. Deepwater formation in the North Atlantic Subpolar Sea (North Atlantic Deep Water: NADW) is affected by changes in ice volume and extent, and regulates the intensity C of the THC; changes in Antarctic Bottom Water (AABW) formation are neglected in this approximation. Deep-water formation in turn affects the system's temperature, and is also affected by it. Reproduced from Ghil, M., Mullhaupt, A., Pestiaux, P., 1987. Deep water formation and Quaternary glaciations, *Climate Dynamics* 2, 1–10.

have formed in the global ocean near the equator; such an overturning circulation of opposite sign to that prevailing today has been dubbed *halothermal*, *S* before *T*. The quantification of the relative effects of *T* and *S* on the oceanic water masses' buoyancy in high and low latitudes is far from complete, especially for paleocirculations; the association of the latter with salinity effects that exceed the thermal ones is thus rather tentative.

Stommel considered a two-box model, with two pipes connecting the two boxes. He showed that the system of two nonlinear, coupled ordinary differential equations that govern the temperature and salinity differences between the two well-mixed boxes, has two stable steady-state solutions, distinguished by the direction of flow in the upper and lower pipes. Stommel's paper was primarily concerned with distinct local convection regimes, and hence vertical stratifications, in the North Atlantic and the Mediterranean (or Red Sea), say. Today, we mainly think of one box as representing the low latitudes and the other one the high latitudes in the global THC.

The next step in the hierarchical modeling of the THC is that of 2D meridional plane models, in which the temperature and salinity fields are governed by coupled nonlinear partial differential equations with two independent space variables, latitude and depth. Given boundary conditions for such a model that is symmetric about the Equator, as are the equations themselves, one expects a symmetric solution, in which water either sinks near the poles and rises everywhere else (thermohaline) or sinks near the Equator and rises everywhere else (halothermal). These

two symmetric solutions would correspond to the two equilibria of Stommel's box model of 1961.

In fact, symmetry breaking can occur, leading gradually from a symmetric two-cell circulation to an antisymmetric one-cell circulation. In between, all degrees of dominance of one cell over the other are possible. A situation lying somewhere between the two seems to resemble most closely the meridional overturning diagram of the Atlantic Ocean in **Figure 2**.

This symmetry breaking can be described by a *pitchfork bifurcation*:

$$\dot{X} = \mu X - X^3 \quad [5]$$

Here X stands for the amount of asymmetry in the solution, so that $X = 0$ is the symmetric branch, and μ is a parameter that measures the stress on the system, in particular a normalized form of the buoyancy flux at the surface. For $\mu < 0$, the symmetric branch is stable, while for $\mu > 0$, $X = 0$ becomes unstable and the two branches $X = \pm \mu^{1/2}$ inherit its stability.

In the 2D THC problem, the left cell dominates on one branch, while the right cell dominates on the other: for a given value of μ , the two stable steady-state solutions—on the $\{X = +\mu^{1/2}\}$ branch and on the $\{X = -\mu^{1/2}\}$ branch—are mirror images of each other. The idealized THC in **Figure 2**, with the North Atlantic Deep Water (NADW) extending to the Southern Ocean's polar front, corresponds to one of these two branches. In theory, therefore, a mirror image circulation, with the Antarctic Bottom Water (AABW) extending to the North Atlantic's polar front, is equally possible.

Table 1 Thermohaline circulation oscillations

Timescale	Phenomena	Mechanism
Interdecadal	3D, wind-driven + thermohaline circulation	– Gyre advection – Localized surface-density anomalies due to surface coupling
Centennial	Loop-type, Atlantic–Pacific circulation	Conveyor-belt advection of high-latitude density anomalies
Millennial	Relaxation oscillation, with “flushes” and superimposed decadal fluctuations	Bottom-water warming, due to high latitude freshening and its braking effect

Bifurcation Diagrams for GCMs

F Bryan was the first, in 1986, to document transition from a two-cell to a one-cell circulation in a simplified ocean GCM with idealized, symmetric forcing. Results of coupled ocean–atmosphere GCMs, however, have led to questions about the realism of more than one stable THC equilibrium. The situation with respect to the THC’s pitchfork bifurcation, as illustrated in eqn [5], is thus subtler than it was with respect to [Figure 1](#) for radiative equilibrium. In the previous section, atmospheric GCMs confirmed essentially the EBM results; the results obtained in climbing the rungs of the modeling hierarchy for the THC are still in need of further clarification.

Internal variability of the THC—with smaller and more regular excursions than the huge and totally irregular jumps associated with bistability—was studied intensively in the late 1980s and the 1990s. These studies placed themselves on various rungs of the modeling hierarchy, from box models through 2D models and all the way to ocean GCMs. A summary of the different kinds of oscillatory variability found in the latter appears in [Table 1](#). Such oscillatory behavior seems to match more closely the instrumentally recorded THC variability, as well as the paleoclimatic records for the recent geological past, than bistability.

The (multi)millennial oscillations interact with variability in the surface features and processes, which are shown in [Figure 2](#). Chen and Ghil, in particular, studied some of the interactions between atmospheric processes and the THC. They used a so-called hybrid coupled model, namely a (horizontally) 2D EBM, coupled to a rectangular box version of the North Atlantic rendered by a low-resolution ocean GCM. This hybrid model’s regime diagram is shown in [Figure 3\(a\)](#). A steady state is stable for high values of the coupling parameter λ_{ao} or of the EBM’s diffusion parameter d . Interdecadal oscillations with a period of 40–50 years are self-sustained and stable for low values of these parameters.

The self-sustained THC oscillations in question are characterized by a pair of vortices of opposite sign that grow and decay in quadrature with each other in the ocean’s upper layers. Their centers follow each other anticlockwise through the northwestern quadrant of the model’s rectangular domain. Both the period and the spatiotemporal characteristics of the oscillation are thus rather similar to those seen in a fully coupled GCM with realistic geometry. The transition from a stable equilibrium to a stable limit cycle, via Hopf bifurcation, in this hybrid coupled model, is shown in [Figure 3\(b\)](#).

Figure 3 Dependence of THC solutions on two parameters in a hybrid coupled model; the two parameters are the atmosphere–ocean coupling coefficient λ_{ao} and the atmospheric thermal diffusion coefficient d . (a) Schematic regime diagram. The full circles stand for the model’s stable steady states, the open circles for stable limit cycles, and the solid curve is the estimated neutral stability curve between the former and the latter. (b) Hopf bifurcation curve at fixed $d = 1.0$ and varying λ_{ao} ; this curve was obtained by fitting a parabola to the model’s numerical simulation results, shown as full and open circles, for the stationary and the periodic GCM solutions, respectively. Reproduced from Chen, F., Ghil, M., 1996. Interdecadal variability in a hybrid coupled ocean–atmosphere model. *Journal of Physical Oceanography* 26, 1561–1578.

Randomness and Nonlinearity

What to Expect

The geometric and the ergodic theories of dynamical systems represent significant achievements of the twentieth century. The foundations of the stochastic calculus in its second half also led to the birth of a rigorous theory of time-dependent random phenomena. Historically, theoretical developments in climate dynamics have been largely motivated by these two complementary approaches, based on the works of Lorenz and that of Hasselmann, respectively.

It now seems clear that these two approaches complement, rather than exclude each other. Incomplete knowledge of small-, subgrid-scale processes, as well as computational limitations, will always require one to account for these processes in a stochastic way. As a result of sensitive dependence on initial data and on parameters, numerical weather forecasts and climate projections are both expressed these days in probabilistic terms. In addition to the intrinsic challenge of addressing the nonlinearity along with the stochasticity of climatic processes, it is thus more convenient—and becoming more and more necessary—to rely on a model's (or set of models') probability density function (PDF) rather than on its individual, pointwise simulations or predictions.

We summarize here the results on the surprisingly complex statistical structure that characterizes stochastic nonlinear systems. This complex structure does provide meaningful physical information that is not described by the PDF alone; it lives on a *random attractor*, which extends the concept of a *strange attractor* and of its *invariant measures* from deterministic to stochastic dynamics.

What One Finds

On the road to including random effects, one needs to realize first that the climate system—as well as any of its subsystems, and on any timescale—is not closed: it exchanges energy, mass, and momentum with its surroundings, whether other subsystems or the interplanetary space and the solid earth. The typical applications of dynamical systems theory to climate variability so far have only taken into account exchanges that are constant in time, thus keeping the model—whether governed by ordinary, partial, or other differential equations—*autonomous*, i.e., the models had coefficients and forcings that were constant in time.

Succinctly, one can write such an autonomous system as

$$\dot{\mathbf{X}} = \mathbf{f}(\mathbf{X}, \boldsymbol{\mu}) \quad [6]$$

where $\mathbf{X}$ now may stand for any state vector or climate field, while $\mathbf{f}$ is a smooth function of $\mathbf{X}$ and of the vector of parameters $\boldsymbol{\mu}$, but does not depend explicitly on time. The characteristic of being autonomous greatly facilitated the analysis of model solutions' properties. For instance, two distinct trajectories, $\mathbf{X}_1(t)$ and $\mathbf{X}_2(t)$, of a well-behaved, smooth autonomous system cannot pass through the same point in phase space, which helps describe the system's phase portrait. So does the fact that we only need to consider the behavior of solutions $\mathbf{X}(t)$ as we let time t tend to $+\infty$: the resulting sets of points are—possibly multiple—equilibria, periodic solutions, and chaotic sets. In the language of dynamical systems theory, these are called, respectively, *fixed points*, *limit cycles*, and *strange attractors*.

We only know too well, however, that the seasonal cycle plays a key role in climate variability on many timescales, while orbital forcing is crucial on the Quaternary timescales of many millennia, and now anthropogenic forcing is of utmost importance on interdecadal timescales. How can one take into account such time-dependent forcings, and analyze the nonautonomous systems, written succinctly as:

$$\dot{\mathbf{X}} = \mathbf{f}(\mathbf{X}, t; \boldsymbol{\mu}) \quad [7]$$

to which they give rise? In eqn [7], the dependence of $\mathbf{f}$ on t may be periodic, $\mathbf{f}(\mathbf{X}, t + P) = \mathbf{f}(\mathbf{X}, t)$ as in various El Niño–Southern Oscillation (ENSO) models, where the period $P = 12$ months, or monotone, $\mathbf{f}(\mathbf{X}, t + \tau) \geq \mathbf{f}(\mathbf{X}, t)$, as in studying scenarios of anthropogenic climate forcing.

To illustrate the fundamental character of the distinction between an autonomous system like eqn [6] and a nonautonomous one like eqn [7], consider the simple scalar version of these two equations:

$$\dot{X} = -\beta X \quad [8]$$

$$\dot{X} = -\beta X + \gamma t \quad [9]$$

respectively. We assume that both systems are dissipative, i.e., $\beta > 0$, and that the forcing is monotone increasing, $\gamma \geq 0$, as would be the case for anthropogenic forcing in the industrial era. Lorenz in his 1963 paper pointed out the key role of dissipativity in giving rise to strange, but attracting solution behavior, while Ghil and Childress in their 1987 book emphasized its importance and pervasive character in climate dynamics. Clearly, the only attractor for the solutions of eqn [6], given any initial point $X(0) = X_0$, is the fixed point $X = 0$, attained as $t \rightarrow +\infty$.

In the case of eqn [9], though, this *forward-in-time approach* yields blowup as $t \rightarrow +\infty$, for any initial point. To make sense of what happens in the case of time-dependent forcing, one introduces instead the *pullback approach*, in which solutions are allowed to still depend on the time t at which we observe them, but also on a time s from which the solution is started, $X(s) = X_0$; presumably $s \ll t$. With this little change of approach, one can easily verify that

$$|X(s, t; X_0) - A(t)| \rightarrow 0 \text{ as } s \rightarrow -\infty \quad [10a]$$

for all t and X_0 , where

$$A(t) = \gamma(t - 1/\beta)/\beta \quad [10b]$$

One thus obtains, in this pullback sense, the intuitively obvious result that the solutions, if started far enough in the past, all approach the attractor set $A(t)$, which has a linear growth in time, thus following the forcing.

Let us return now to the more general, nonlinear case of eqn [7] and add not only deterministic time dependence $\mathbf{f}(\mathbf{X}, t)$, but also random forcing,

$$d\mathbf{X} = \mathbf{f}(\mathbf{X}, t)dt + \mathbf{g}(\mathbf{X})d\eta \quad [11]$$

where $\eta = \eta(t, \omega)$ represents a Wiener process—while $d\eta$ is commonly referred to as 'white noise'—and ω labels the particular realization of this random process. The case $\mathbf{g}(\mathbf{X}) = \text{const.}$ is the case of *additive noise*, while in the case of $\partial \mathbf{g}(\mathbf{X}) / \partial \mathbf{X} \neq 0$ one speaks of *multiplicative noise*. The distinction

Figure 4 Schematic diagram of a random attractor $A(\omega)$ and of the pullback attraction to it; here ω labels the particular realization of the random process $\theta(t)\omega$ that drives the system. We illustrate the evolution in time t of the random process $\theta(t)\omega$ (light solid black line at the bottom); the random attractor $A(\omega)$ itself (yellow band in the middle) with the ‘snapshots’ $A(\omega) = A(\omega; t = 0)$ and $A(\omega; t)$ (the two vertical sections, heavy solid); and the flow of an arbitrary set B from ‘pullback times’ $t = -\tau_2$ and $t = -\tau_1$ onto the attractor (heavy blue arrows). Reproduced from Ghil, M., Chekroun, M.D., Simonnet, E., 2008. Climate dynamics and fluid mechanics: Natural variability and related uncertainties, invited survey paper for Special Issue on “The Euler Equations: 250 Years On” *Physica D* 237: 2111–2126, doi:10.1016/j.physd.2008.03.036.

between dt and $d\eta$ in eqn [11] is necessary since, roughly speaking and following Einstein’s celebrated 1905 paper on Brownian motion, it is the variance of a Wiener process that is proportional to time and thus $d\eta \propto (dt)^{1/2}$.

In the case of random forcing, the concepts introduced by the simple example of eqns [10a] and [10b] above can be illustrated by the random attractor $A(\omega)$ (yellow band) of Figure 4. In the figure, $d\eta(t, \omega) = \theta(t)\omega$ is the random process that drives the system (light solid black line) and the pullback attraction is depicted by the flow of an arbitrary set B from ‘pullback times’ $t = -\tau_2$ and $t = -\tau_1$ onto the attractor (heavy blue arrows).

More explicitly, one can see in Figure 5 four ‘snapshots’ $\{A_j(\omega) = A(\omega; t = t_j); j = 1, 2, 3, 4\}$ that correspond to the vertical cross sections (heavy solid) in the attractor of Figure 4; a short video, from which these snapshots are taken, is also linked to this article. These snapshots were calculated for the random attractor $A(\omega)$ of a stochastically perturbed Lorenz system, given by

$$\begin{cases} dX = P(Y - X)dt + \sigma_0 X d\eta \\ dY = (rX - Y - XZ)dt + \sigma_0 Y d\eta \\ dZ = (-bZ + XY)dt + \sigma_0 Z d\eta \end{cases} \quad [12]$$

The parameters r , P , and b in eqn [12] have the usual meanings for 2D thermal convection: $r = R/R_c$ is the Rayleigh number R normalized by its critical value R_c at the onset of convection, P is the Prandtl number, and b is a normalized wave number for the most unstable wave at the onset of convection. The noise in this case is multiplicative: its intensity $\sigma_0 = 0.5$ is multiplied in each one of the three coupled, nonlinear equations above by the corresponding variables X , Y , or Z .

Supplementary data related to this article can be found at <http://dx.doi.org/10.1016/B978-0-12-382225-3.00110-9>.

To be precise, what is plotted in Figure 5, and in the associated video at <http://dx.doi.org/10.1016/B978-0-12-382225-3.00110-9>, is the density of the invariant measure $\nu(\omega)$

supported on the random attractor of the stochastically perturbed Lorenz system in eqn [12]. This measure indicates the probability of trajectories winding up in a particular region of phase space and it is very highly concentrated on the attractor, as inferred from the huge range of density values: the color bar in the figure is on a logarithmic scale, and extends over more than 10 orders of magnitude. The situation is thus very different from that expected when studying additive noise; in that case, the noise tends to smear out the fine, Cantor-set-like structure of the deterministic, strange attractor, and the associated PDF is supported on a set of nonzero volume.

It hardly needs saying that additive noise has been studied in climate dynamics much more extensively since it was easier to do so. Studies along these lines were suggested by the simple Brownian motion analogy of ‘weather = water molecules’ and ‘climate = pollen particle’, as proposed by Hasselmann in 1976. Across the hierarchy of climate models discussed in the previous two sections of this article, however, it is clear that small and fast scales of motion do not enter exclusively in an additive manner: they pop up in many, if not all terms of the governing equations, as summarized in eqn [11]. The insights offered, therefore, by Figure 5 and the video are likely to be of interest across the hierarchy of models, all the way up to coupled GCMs and Earth system models.

The invariant measure in Figure 5 exhibits amazing complexity, with fine, very intense filamentation: There is no fuzziness whatsoever in the topological structure of this filamentation, which does evoke the Cantor set foliation of the deterministic attractor. This fine structure strongly suggests that an object of vanishing volume supports this measure, i.e., that the random attractor $A(\omega)$ of eqn [12] has—like the strange attractor of the classical, deterministic version, with $\sigma_0 = 0$ —dimension smaller than 3.

Such complexity, however, should not hide the fact that the theory of random dynamical systems provides robust tools for studying the parameter dependence of a nonlinear, randomly perturbed system’s various ‘metrics’. These metrics can include global quantities, such as mean temperature or total energy, but also much finer functionals of the state of the system, such as regional temperatures or precipitation. In addition, this theory can help improve prediction of future system properties, by relying on a judicious combination of the history of its slow and fast behavior.

Concluding Remarks

A complete theory of climate variability, across the entire range of timescales of interest, is still in the future. We have shown, though, that powerful conceptual and numerical tools exist in order to organize the emerging knowledge so far. The approach described herein relies on applying systematically dynamical systems theory, both deterministic and stochastic, across a hierarchy of models, from the simplest toy models to the most detailed, coupled GCMs. This approach has progressed from its first modest steps, taken almost exactly half a century ago, to the analysis of the behavior of atmospheric, oceanic, and coupled GCMs over

Figure 5 Four snapshots of the stochastically perturbed Lorenz (1963) model's random attractor $A(\omega)$ and the invariant measure $\nu(\omega)$ supported on it. The parameter values are the classical ones—normalized Rayleigh number $r = 28$, Prandtl number $P = 10$, and normalized wave number $b = 8/3$ —while the noise intensity is $\sigma_0 = 0.5$ and the time step is $\delta t = 5 \times 10^{-3}$. The color bar used is on a log-scale and quantifies the probability to end up in a particular region of phase space; shown is a projection of the 3D phase space (X, Y, Z) onto the (X, Z) plane. Notice the complex, interlaced filament structures between highly (yellow) and moderately (red) populated regions. The time interval Δt between two successive snapshots—moving from left to right and top to bottom—is $\Delta t = 0.0875$. Note that the support of the invariant measure $\nu(\omega; t)$ may change quite abruptly, from time t to time $t + \Delta t$; see the related short video at <http://dx.doi.org/10.1016/B978-0-12-382225-3.00110-9>. Weakly populated regions cover an important part of the random attractor and are, in turn, entangled with regions that have near-zero probability (black). Reproduced from Chekroun, M.D., Simonnet, E., Ghil, M., 2011. Stochastic climate dynamics: Random attractors and time-dependent invariant measures. *Physica D* 240 (21), 1685–1700. <http://dx.doi.org/10.1016/j.physd.2011.06.005>.

the last two decades. Especially, interesting strides have been taken over the last decade in studying the interaction of the faster timescales with the slower ones, within a genuinely nonlinear framework.

Climate Variability: North Atlantic and Arctic Oscillation

JW Hurrell, National Center for Atmospheric Research, Boulder, CO, USA

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

A leading pattern of weather and climate variability over the Northern Hemisphere is the North Atlantic oscillation (NAO). The NAO refers to a redistribution of atmospheric mass between the Arctic and the subtropical Atlantic, and swings from one phase to another to produce large changes in surface air temperature, winds, storminess, and precipitation over the Atlantic as well as the adjacent continents. The NAO also affects the ocean through changes in heat content, gyre circulations, mixed layer depth, salinity, high-latitude deepwater formation, and sea ice cover. A better understanding of how the NAO responds to external forcing, including increasing greenhouse gas concentrations, is thus crucial.

Introduction

Changes in naturally occurring patterns or 'modes' of atmospheric and oceanic variability, such as the El Niño southern oscillation (ENSO) and the North Atlantic oscillation (NAO), orchestrate large variations in weather and climate over much of the globe on interannual and longer timescales. For instance, significant changes in regional temperature and precipitation from one year (or one decade) to the next can be attributed to changes in the phase and amplitude of these two dominant patterns of variability. Moreover, it has been argued that the spatial pattern of the response to anthropogenic forcing may project principally onto such modes of natural climate variability.

Modal variability thus forms a natural subject on which the investigators of climate and climate impact science can collaborate. This collaboration is also required to determine the most relevant effects for society of global change on regional natural and managed ecosystems. This article focuses on the extratropical Northern Hemisphere (NH) and it begins with a basic description of the spatial structure of extratropical climate and climate variability. It includes a discussion of how the NAO is defined and its impacts on surface temperature, precipitation, storms, the underlying ocean, and sea ice. The article concludes with a brief discussion of outstanding issues and future challenges, especially related to the mechanisms that most likely govern NAO variability.

The Spatial Structure of Extratropical Climate and Climate Variability

Climate variability is usually characterized in terms of 'anomalies,' where an anomaly is the difference between the instantaneous state of the climate system and the climatology (the mean state computed over many years representative of the era under consideration). Since the spatial structure of climate variability in the extratropics is strongly seasonally dependent, it is useful to briefly examine the seasonal evolution of the mean state upon which the climate variations are superimposed.

The Mean State and Planetary Waves

Large changes in the mean distribution of sea level pressure (SLP) over the NH are evident from winter (December–

February) to summer (June–August). Perhaps, most noticeable are those changes over the Asian continent related to the development of the Siberian anticyclone during winter and the monsoon cyclone over Southeast Asia during summer (Figure 1). Over the northern oceans, subtropical anticyclones dominate during summer, with the Azores high-pressure system covering nearly all of the North Atlantic. These anticyclones weaken and move equatorward by winter, when the high-latitude Aleutian and Icelandic low-pressure centers predominate.

Because air flows counterclockwise around low pressure and clockwise around high pressure in the NH, westerly flow across the middle latitudes of the Atlantic sector occurs throughout the year (Figure 2). The vigor of the flow is related to the north–south pressure gradient, so the surface winds are strongest during winter when they average near 5 m s^{-1} from the eastern United States across the Atlantic onto northern Europe. These middle latitude westerly winds extend throughout the troposphere and reach their maximum (up to 40 m s^{-1}) at a height of about 12 km. This 'jet stream' roughly coincides with the path of storms (atmospheric disturbances operating on timescales of days) traveling between North America and Europe. Over the subtropical Atlantic the prevailing surface northeasterly trade winds are relatively steady but strongest during boreal summer.

In the middle troposphere ($\sim 5\text{--}6 \text{ km}$), the boreal winter map of the geopotential height field reveals a westward tilt with elevation of the high-latitude surface cyclones and anticyclones (Figure 3). Two low-pressure troughs and two high-pressure ridges are evident: the troughs are located over northeastern Canada and just east of Asia, and the ridges are positioned just west of Europe and over western North America. These strong zonal asymmetries reflect the so-called 'stationary waves' that are forced primarily by the continent–ocean heating contrasts and the presence of the Rocky and Himalayan mountain ranges. In summer, the flow is much weaker and more symmetric, consistent with a much more uniform equator-to-pole distribution of solar radiation.

Although the planetary-scale wave patterns (Figure 3) are geographically anchored, they do change in time either because the heating patterns in the atmosphere vary or because of internal (chaotic) processes. The amplitude and structure of the variability of the seasonal mean 500-hPa geopotential height field (Figure 4) is characterized by a strong longitudinal

Figure 1 Mean SLP for (top) boreal winter (December–February) and (bottom) boreal summer (June–August). The data come from the NCEP/NCAR reanalysis project over 1958–2006.

dependence with maximum temporal variance over the northern oceans, especially during boreal winter. The frequency dependence of the winter pattern is subtle: maps of the variability of monthly mean data, or data filtered to retain fluctuations within specific frequency bands (e.g., 60–180 days), also exhibit distinct variance maxima at 500 hPa over the Atlantic and Pacific Oceans, although the longitudinal contrasts become increasingly apparent as longer timescales are examined. In comparison, throughout most of the NH, the standard deviations of boreal summer 500 hPa heights are only about half as large as those of the wintertime means (Figure 4).

Teleconnections: the PNA and the NAO

A consequence of the transient behavior of the atmospheric planetary-scale waves is that anomalies in climate on seasonal timescales typically occur over large geographic regions. Some

regions may be cooler or perhaps drier than average, while at the same time thousands of kilometers away, warmer and wetter conditions prevail. These simultaneous variations in climate, often of opposite sign, over distant parts of the globe are commonly referred to as ‘teleconnections’ in the meteorological literature. Though their precise nature and shape vary to some extent according to the statistical methodology and the data set employed in the analysis, consistent regional characteristics that identify the most conspicuous patterns emerge.

Arguably the most prominent teleconnections over the NH are the NAO and the Pacific–North American (PNA) patterns. Both patterns are of largest amplitude during the boreal winter months, and their mid-tropospheric spatial structure is illustrated most simply through one-point correlation maps (Figure 5). These maps are constructed by correlating the 500-hPa height time series at a ‘reference gridpoint’ with the corresponding time series at all gridpoints. The PNA teleconnection pattern has four centers of action. Over the North Pacific Ocean, geopotential height fluctuations near the Aleutian Islands vary out-of-phase with those to the south, forming a seesaw pivoted along the mean position of the Pacific subtropical jet stream (Figure 2). Over North America, variations in geopotential height over western Canada and the northwestern United States are negatively correlated with those over the southeastern United States, but are positively correlated with the subtropical Pacific center. The significance of the locations and the respective phases of the four centers of the PNA is their relation to the mean atmospheric circulation (Figure 3). Variations in the PNA pattern represent variations in the waviness of the atmospheric flow in the western half-hemisphere and thus the changes in the north–south migration of the large-scale Pacific and North American air masses and their associated weather.

On interannual timescales, atmospheric circulation anomalies over the North Pacific, including the PNA, are linked to changes in tropical Pacific sea surface temperatures (SSTs) associated with the ENSO phenomenon. This association reflects mainly the dynamical teleconnection to higher latitudes forced by deep convection in the tropics. The PNA pattern is sometimes viewed, then, as the extratropical arm of ENSO. Significant variability of the PNA occurs even in the absence of ENSO, however, indicating that the PNA is an ‘internal’ mode of atmospheric variability.

Similarly, the NAO does not owe its existence to coupled ocean–atmosphere–land interactions, as is evident from climate model experiments that do not include SST, sea ice, or land surface variability. In contrast to the wavelike appearance of the PNA, the NAO is primarily a north–south dipole characterized by simultaneous out-of-phase height anomalies between temperate and high latitudes over the Atlantic sector (Figure 5). Both the NAO and PNA are also reflected in the spatial patterns of the two leading empirically determined orthogonal functions (EOFs) of NH boreal winter 500-hPa height (not shown). The NAO also dominates the leading EOF of the NH SLP field. Analyzing SLP allows for the longer term behavior of the NAO to be evaluated, as a long series of SLP charts over the NH begin in 1899, in contrast to 500-hPa height charts that are confined to after 1947. Moreover, even longer instrumental records of SLP variations are available, especially from European stations. Thus, in the following, the spatial

Figure 2 Mean vector winds for (top) boreal winter (December–February) and (bottom) boreal summer (June–August) for (left) 1000 hPa and (right) 200 hPa over 1958–2006. The scaling vectors in meters per second are indicated in the boxes.

structure and time evolution of the NAO are examined in more detail from SLP records.

The Spatial Signature of the NAO

There is no single way to ‘define’ the NAO. One approach is through conceptually simple one-point correlation maps (Figure 5), identifying the NAO by regions of maximum negative correlation over the North Atlantic. Another technique is EOF (or principal component (PC)) analysis. In this approach, the NAO is identified from the eigenvectors of the cross-covariance (or cross-correlation) matrix, computed from the time variations of the gridpoint values of SLP or some other climate variable. The eigenvectors, each constrained to be spatially and temporally orthogonal to the others, are then scaled according to the amount of total data variance they explain. This linear approach assumes preferred atmospheric circulation states come in pairs, in which anomalies of opposite polarity have the same spatial structure. In contrast, climate anomalies can also be identified by cluster analysis techniques, which search for recurrent patterns of a specific amplitude and sign. Clustering algorithms identify weather or climate ‘regimes,’ which correspond to peaks in the probability density

function of the climate phase space. In the following, the spatial patterns of the NAO are compared as estimated from both traditional EOF and clustering techniques.

EOF Analysis of North Atlantic SLP

The leading eigenvectors of the cross-covariance matrix calculated from seasonal (3-month average) SLP anomalies in the North Atlantic sector (20–70° N; 90° W–40° E) are illustrated in Figure 6. The patterns are very similar if based on the cross-correlation matrix (not shown).

The largest amplitude anomalies in SLP occur during the boreal winter months; however, throughout the year the leading pattern of variability is characterized by a surface pressure dipole, and thus may be viewed as the NAO, although the spatial pattern is not stationary. Since the eigenvectors are, by definition, structured to explain maximum variance, it is expected that the ‘center of actions’ of the leading EOFs will coincide with the regions of strongest variability, and the movement of those regions through the annual cycle is reflected in Figure 6.

The NAO is the only teleconnection pattern evident throughout the year in the NH. During the winter season (December–February), it accounts for more than one-third of

500-hPa Geopotential height

Figure 3 Mean 500-hPa geopotential height for (top) boreal winter (December–February) and (bottom) boreal summer (June–August), indicated by the gray contours for every 120-geopotential meters (gpm), over 1958–2006. The colors indicate departures from the zonal average.

the total variance in SLP over the North Atlantic and appears with a slight northwest to southeast orientation. In the so-called ‘positive phase’ (depicted), higher than normal surface pressures south of 55° N combine with a broad region of anomalously low pressure throughout the Arctic to enhance the climatological meridional pressure gradient (Figure 1). The largest amplitude anomalies occur in the vicinity of Iceland and across the Iberian Peninsula. The positive phase of the NAO is associated with stronger-than-average surface westerlies across the middle latitudes of the Atlantic onto Europe, with anomalous southerly flow over the eastern United States and anomalous northerly flow across the Canadian Arctic and the Mediterranean (Figure 7).

By boreal spring (March–May), the NAO appears as a north–south dipole with a southern center of action near the Azores. Both the spatial extent and the amplitude of the SLP anomalies are smaller than during winter, but not by much, and the leading EOF explains 30% of the SLP variance. The

 $\sigma(z)$ 500 hPa

Figure 4 Interannual variability of 500-hPa geopotential height for (top) boreal winter (December–February) and (bottom) boreal summer (June–August) over 1958–2006. The contour increment is 10 gpm.

amplitude, spatial extent, and the percentage of total SLP variability explained by the NAO reach minimums during the summer (June–August) season, when the centers of action are substantially north and east relative to winter. By fall (September–November), the NAO takes on more of a southwest-to-northeast orientation, with SLP anomalies in the northern center of action comparable in amplitude to those during spring.

That the spatial pattern of the NAO remains largely similar throughout the year does not imply that it also tends to persist in the same phase for long. To the contrary, it is highly variable, tending to change its phase from one month to another, and its longer term time-average behavior reflects the combined effect of residence time in any given phase and its amplitude therein.

Most studies of the NAO focus on the NH winter months, when the atmosphere is most active dynamically and perturbations grow to their largest amplitudes. As a result, the influence of the NAO on surface temperature and precipitation is likely to be greatest at this time of year. However, coherent

Figure 5 One-point correlation maps of 500-hPa geopotential heights for boreal winter (December–February) over 1958–2006. In the top panel, the reference point is 45° N, 165° W, corresponding to the primary center of action of the PNA pattern. In the lower panel, the NAO pattern is illustrated based on the reference point of 65° N, 30° W.

fluctuations of surface pressure, temperature, cloudiness, and precipitation occur throughout the year over the North Atlantic, and decadal and longer term variability is not confined to winter. Moreover, the vigorous wintertime NAO can interact with the slower components of the climate system (the ocean, in particular) to leave persistent surface anomalies into the ensuing parts of the year that may significantly influence the evolution of the climate.

EOF Analysis of NH SLP

A well-known shortcoming of EOF analysis is that eigenvectors are mathematical constructs, constrained by their mutual orthogonality and the maximization of variance over the entire analysis domain. There is no guarantee, therefore, that they represent physical/dynamical modes of the climate system. An EOF analysis, for instance, will not clearly reveal two patterns that are linearly superposed if those patterns are not

orthogonal. Moreover, the loading values of EOFs do not reflect the local behavior of the data: values of the same sign at two different spatial points in an EOF do not imply that those two points are significantly correlated. This means that the pattern structure of any particular EOF must be interpreted with care. These issues have been at the center of a debate over whether or not the NAO is a regional expression of a larger scale (hemispheric) mode of variability known as the NH annular mode (NAM) or, previously, the Arctic oscillation (AO).

The NAM is defined as the first EOF of NH (20–90° N) winter SLP data (Figure 8, upper panel, based on the cross-covariance matrix). It explains 23% of the extended winter-mean (December–March) variance, and it is clearly dominated by the NAO structure in the Atlantic sector. Although there are some subtle differences from the regional pattern (Figure 8, lower panel) over the Atlantic and Arctic, the main difference is larger amplitude anomalies over the North Pacific of the same sign as those over the Atlantic. This feature gives the NAM an almost annular (or zonally symmetric) structure that reflects a more hemispheric-scale meridional seesaw in SLP between polar and middle latitudes. Some have argued that the NAM is a fundamental structure of NH climate variability and that the ‘regional’ NAO reflects the modification of the annular mode by zonally asymmetric forcings, such as topography and land–ocean temperature contrasts. It would then follow that the annular mode perspective is critical in order to understand the processes that give rise to NAM (or NAO) variations. For instance, the leading wintertime pattern of variability in the lower stratosphere is clearly annular (not shown), but the SLP anomaly pattern that is associated with it is confined almost entirely to the Arctic and Atlantic sectors and coincides with the spatial structure of the NAO.

Cluster Analysis of North Atlantic SLP

The dynamical signature of interannual variability in the North Atlantic domain can also be examined through nonlinear approaches, such as cluster analysis or nonlinear PC analysis. Here the former one was applied to 57 years of daily SLP data from December to March. Briefly, cluster analysis is a multivariate statistical technique that groups together the daily SLP maps into a small number of representative states (or regimes) according to an objective criterion of similarity. Note that by construction, the percentage of occurrence of the identified clusters sums to 100.

The clustering algorithm applied over the Atlantic domain (20–70° N; 90° W–40° E) identifies four winter climate regimes in SLP (Figure 9). Two of them correspond to the negative and positive phases of the NAO, while the third and fourth regimes display strong anticyclonic ridges over Scandinavia (the ‘blocking’ regime) and off western Europe (the ‘Atlantic ridge’ regime). The latter bears some resemblance to another prominent atmospheric teleconnection: the East Atlantic pattern. All four regimes occur with about the same frequency (20–30% of all winter days), although these numbers are sensitive to the period of analysis, reflecting that the dominance of certain regimes over others varies over time (see Section Temporal Variability of the NAO).

In contrast to the typical NAO pattern identified through linear approaches (e.g., Figures 5 and 6), some interesting

Figure 6 Leading EOF1 of the seasonal mean SLP anomalies in the North Atlantic sector (20–70° N, 90° W–40° E), and the percentage of the total variance they explain. The patterns are displayed in terms of amplitude (hPa), obtained by regressing the hemispheric SLP anomalies upon the leading PC time series. The data cover 1899–2006.

spatial asymmetries are evident in [Figure 9](#). Most striking is the difference in the position of the pressure anomalies between the two NAO regimes: in particular, the eastward shift (by $\sim 30^\circ$ longitude) and northeastward extension of the subpolar SLP anomalies in the positive relative to the negative regime. These spatial asymmetries are not dependent on the analysis period: they are evident in the subperiods of the SLP data set. Similar results, indicating a nonlinearity in NAO variability, are found when the PC time series of the leading EOF of Atlantic SLP is used to define and average together positive and negative index winters (not shown). The robustness of the eastward displacement of the NAO in positive regime months has interesting implications for conclusions drawn from some climate model studies on how increasing greenhouse gas (GHG) concentrations might affect the spatial structure of the NAO. For instance, some studies have concluded that future enhanced GHG forcing might result in an eastward displacement of the NAO centers of action. The results from the regime analysis, however, suggest that longitudinal shifts could arise from the preferential excitement of positive NAO regimes,

which are intrinsically displaced eastward, rather than a static shift of the Atlantic pressure centers.

Temporal Variability of the NAO

Since there is no unique way to define the spatial structure of the NAO, it follows that there is no universally accepted index to describe the temporal evolution of the phenomenon. Most modern NAO indices are derived either from the simple difference in surface pressure anomalies between various northern and southern locations or from the PC time series of the leading (usually regional) EOF of SLP. Many examples of the former exist, usually based on instrumental records from individual stations near the NAO centers of action, but sometimes from gridded SLP analyses.

A disadvantage of station-based indices is that they are fixed in space. Given the movement of the NAO centers of action through the annual cycle ([Figure 6](#)), such indices can only adequately capture NAO variability for parts of the year.

Figure 7 The amplitude of boreal winter (December–February) 1000-hPa scalar wind speed (color) and vector wind (arrows) associated with a one standard deviation change of an NAO index, defined as the PC time series of the leading EOF of Atlantic sector SLP (as in [Figure 6](#)). The plot is constructed from winter data from the NCEP/NCAR reanalyses over 1958–2006. The color scale is in units of meters per second, and the scaling vector (lower right) is 1 m s^{-1} .

Moreover, individual station pressures are significantly affected by small-scale and transient meteorological phenomena not related to the NAO and, thus, contain noise.

An advantage of the PC time series approach is that such indices are more optimal representations of the full NAO spatial pattern; yet, as they are based on gridded SLP data, they can only be computed for short (relative to some station records) periods of time, depending on the data source. Below a station-based index was compared to the PC time series of the leading EOF (PC1) of both Atlantic sector and NH SLP. The latter is the NAM index. The time history of occurrence of the NAO regimes identified in [Figure 9](#) was presented. All comparisons are for the winter (December–March) season.

A widely used winter-mean NAO station index is shown in [Figure 10](#) (upper panel). Positive values of the index indicate stronger-than-average westerlies over the middle latitudes. The station-based index for the winter season agrees well with PC1 of the Atlantic sector SLP: the correlation coefficient between the two is 0.92 over the common period since 1899, indicating that the station-based index adequately represents the time variability of the winter-mean NAO spatial pattern. Moreover, it correlates with the NAM index (lower panel) at 0.85, while the correlation of the two PC1 time series is 0.95. These results again emphasize that the NAO and NAM reflect essentially the

same mode of tropospheric variability. When intraseasonal anomalies are considered by stringing together the individual winter months, the correlation coefficient between the two PC1 time series is reduced slightly to 0.89.

An important conclusion from [Figure 10](#) is that there is little evidence for the NAO to vary on any preferred time scale. Large changes can occur from one winter to the next, as well as from one decade to the next. The power spectra of the indices in [Figure 10](#) are only slightly 'red,' with power increasing with period (not shown). When the spectral characteristics of the NAO are examined using daily data (not shown), its temporal evolution is generally consistent with a stochastic (Markov or first-order autoregressive) process with a fundamental time-scale of about 10 days. This then means that observed inter-annual and longer timescale NAO fluctuations ([Figure 10](#)) could primarily be a statistical remnant of the energetic weekly variability. This 'climate noise paradigm' fails, however, to explain the enhanced interannual NAO variability observed over the last half of the twentieth century, when a role for forcing by other climate system components is likely. Indeed, numerous studies have argued that variations in heat exchange between the atmosphere and ocean, sea ice and/or land systems could modulate NAO variability on seasonal to multi-decadal timescales.

Figure 8 Leading EOF1 of the winter (December–March) mean SLP anomalies over (top) the NH (20–90° N) and (bottom) the North Atlantic sector (20–70° N, 90° W–40° E), and the percentage of the total variance they explain. The patterns are displayed in terms of amplitude (hPa), obtained by regressing the hemispheric SLP anomalies upon the leading PC time series. The data cover 1899–2006. The dots in the bottom panel represent the locations of Lisbon, Portugal, and Stykkisholmur, Iceland used in the station-based NAO index of Hurrell (1995; see [Figure 10](#)).

Another index, the time history of the occurrence of NAO, blocking and Atlantic ridge regimes ([Figure 8](#)), offers a different perspective ([Figure 11](#)). Plotted is the frequency of occurrence of each regime in units of the number days a regime is present within a given winter (December–March) season. For the two NAO regimes, as for the more conventional indices, strong interannual variability is evident, and there are periods when one NAO regime occurs almost to the exclusion of the other. For instance, very few positive NAO regime occurrences are found during the 1960s, while very few negative regime occurrences were observed during the 1990s, consistent with the upward trend in traditional NAO indices over this period ([Figure 10](#)).

The regime analysis also illustrates two other important points. First, there is a large amount of within-season variance in the atmospheric circulation of the North Atlantic. Most winters are not dominated by any particular regime; rather, the atmospheric circulation anomalies in one month might resemble the positive index phase of the NAO, while in another month, they resemble the negative index phase or some other pattern altogether. Since 2001, for instance, more winter days over the North Atlantic have been characterized by circulation anomalies that project onto the Atlantic ridge or blocking patterns than either phase of the NAO ([Figure 11](#)). Moreover, roughly the same numbers of negative and positive NAO index days have occurred over this period, consistent with the small, winter-mean values of conventional NAO indices ([Figure 10](#)). Thus, the second point is that although the NAO is the dominant pattern of atmospheric circulation variability over the North Atlantic, it explains only a fraction of the total variance, and most winters cannot be characterized solely by the canonical NAO pattern in [Figure 6](#).

Impacts of the NAO

The NAO exerts a dominant influence on wintertime temperatures across much of the NH. Surface air temperature and SST across wide regions of the North Atlantic Ocean, North America, the Arctic, Eurasia, and the Mediterranean are significantly correlated with NAO variability. These changes, along with related changes in storminess and precipitation, ocean heat content, ocean currents and their related heat transport, and sea ice cover, have significant impacts on a wide range of human activities as well as on marine, freshwater, and terrestrial ecosystems. In the following, a very brief overview of these impacts is presented.

Storms and Precipitation

Changes in the mean circulation patterns over the North Atlantic associated with the NAO are accompanied by changes in the intensity and number of storms, their paths, and their weather. During winter, a well-defined storm track connects the North Pacific and North Atlantic basins, with maximum storm activity over the oceans. Positive NAO index winters are associated with a northeastward shift in the Atlantic storm activity with enhanced activity from Newfoundland into northern Europe and a modest decrease in activity to the south. Positive NAO index winters are also typified by more intense and frequent storms in the vicinity of Iceland and the Norwegian Sea.

The ocean exhibits a marked response to long-lasting shifts in the storm climate. For instance, the very persistent and positive NAO index winters of the 1990s were associated with increased wave heights over the northeast Atlantic. Such changes have consequences for the regional ecology, as well as for the operation and safety of shipping, offshore industries, such as oil and gas exploration, and coastal development.

Changes in the mean flow and storminess associated with swings in the NAO index are also reflected in pronounced changes in the transport and convergence of atmospheric moisture and, thus, the distribution of precipitation ([Figure 12](#)). Winters tend to be dry over much of Greenland

Figure 9 Boreal winter (December–March) climate regimes in SLP (hPa) over the North Atlantic domain (20–70° N, 90° W–40° E) using daily data over 1950–2006. The percentage at the top right of each panel expresses the frequency of occurrence of a cluster out of all winter days since 1950. The contour interval is 2 hPa.

and the Canadian Arctic during high NAO index winters. Drier winter conditions of the same magnitude also occur over much of central and southern Europe, the Mediterranean and parts of the Middle East, whereas more precipitation than normal falls from Iceland through Scandinavia.

Surface Temperature and SST

The NAO exerts a dominant influence on wintertime temperatures across much of the NH. Surface air temperature and SST across wide regions of the North Atlantic Ocean, North America, the Arctic, Eurasia, and the Mediterranean are significantly correlated with NAO variability. Such changes in surface temperature (and related changes in rainfall and storminess) can have significant impacts on a wide range of human activities as well as on marine and terrestrial ecosystems.

When the NAO index is positive, enhanced westerly flow across the North Atlantic during winter moves relatively warm (and moist) maritime air over much of Europe and far downstream across Asia, while stronger northerlies over Greenland and northeastern Canada carry cold air southward and decrease land temperatures and SST over the northwest Atlantic (Figure 13). Temperature variations over North Africa and the Middle East (cooling), as well as North America (warming),

associated with the stronger clockwise flow around the subtropical Atlantic high-pressure center are also notable.

The pattern of temperature change associated with the NAO is important. Because the heat storage capacity of the ocean is much greater than that of the land, changes in continental surface temperatures are much larger than those over the oceans, so they tend to dominate average NH (and global) temperature variability. Given especially the large and coherent NAO signal across the Eurasian continent from the Atlantic to the Pacific (Figure 13), it is not surprising that NAO variability explains about one-third of the NH interannual surface temperature variance during winter.

Over the oceans, it has long been recognized that fluctuations in SST and the strength of the NAO are related. The leading pattern of SST variability during boreal winter (not shown) consists of a tripolar structure marked, in one phase, by a cold anomaly in the subpolar North Atlantic, a warm anomaly in the middle latitudes centered off Cape Hatteras, and a cold subtropical anomaly between the equator and 30° N. This structure suggests that the SST anomalies are driven by changes in the air–sea heat exchanges and surface wind-induced Ekman currents associated with NAO variations. The relationship is indeed strongest when the NAO index leads an index of the SST variability by several weeks, which highlights

Figure 10 Normalized indices of the mean winter (December–March) NAO through 2011 constructed from SLP data. In the top panel, the index is based on the difference of normalized SLP between Lisbon, Portugal, and Stykkisholmur/Reykjavik, Iceland. The average winter SLP data at each station were normalized by the division of each seasonal pressure by the long-term mean (1864–1983) standard deviation. In the middle and lower panels, the index is the PC time series of the leading EOF of Atlantic sector and NH SLP, respectively. The heavy solid lines represent the indices smoothed to remove fluctuations with periods less than 4 years. The indicated year corresponds to the January of the winter season (e.g., 1990 is the winter of 1989/1990).

the well-known result that large-scale SST over the extratropical oceans responds to atmospheric forcing on monthly and seasonal timescales. Compositing North Atlantic SST on high and low NAO index winters clearly illustrates the aforementioned tripole pattern of SST change (Figure 14).

Over longer periods, persistent SST anomalies also appear to be related to persistent anomalous patterns of SLP, including those associated with the NAO, but the mechanisms whereby the atmosphere forces SST anomalies on decadal and longer timescales are different from those on interannual timescales. On decadal and longer timescales, the ocean adjusts dynamically to the overlying changes in wind stress curl, both locally via Ekman pumping and nonlocally through changes in the gyre-scale circulation. This dynamical adjustment alters the horizontal and vertical oceanic heat transports, which in turn impact SST. It is quite likely, for instance, that sustained NAO forcing results in a basin-wide SST response in which the northern and subtropical parts of the tripolar pattern merge. There is also evidence for a northward shift in the position of the Gulf Stream during the positive phase of the NAO, consistent with Sverdrup adjustment of the ocean gyre circulation.

Subsurface Ocean Changes

Subsurface ocean observations more clearly depict long-term climate variability, because the effect of the annual cycle and month-to-month variability in the atmospheric circulation

Figure 11 The time history of occurrence of the NAO, Atlantic ridge, and blocking regimes (see Figure 9) over 1950–2006. The vertical bars give the number of days in each winter (December–March) season that the given regime is present. The indicated year corresponds to the January of the winter season (e.g., 1990 is the winter of 1989/1990).

Figure 12 Changes in mean winter (December–March) precipitation (millimeters per day) associated with a one standard deviation change in the NAO index, defined as in the middle panel of [Figure 10](#). The precipitation data cover 1979 through 2010.

Figure 13 Changes in mean winter (December–March) air temperature (°C) associated with a one standard deviation change in the NAO index, defined as in the middle panel of [Figure 10](#). The temperature data cover 1980 through 2010.

Figure 14 Difference in mean winter (December–March) SST between years when the NAO index exceeds one standard deviation over 1950–2010. The NAO index is defined as in the middle panel of [Figure 10](#).

decays rapidly with depth. These measurements are much more limited than surface observations, but over the North Atlantic they too indicate fluctuations that are coherent with the low-frequency winter NAO index to depths of 400 m.

Oceanic mixed layer depth (MLD) is an important physical factor influencing marine biological productivity and ecosystem dynamics. MLD is influenced by atmospheric and oceanic conditions through wind-induced vertical mixing, heat exchange, and upwelling. The response of the winter MLD to the NAO, estimated by compositing winter months

(December–March) over 1955–2003, consists of a region of negative anomalies (shallower-than-normal mixed layers) extending across much of the middle North Atlantic from the southeastern United States to Spain and a region of weaker positive anomalies to the south. ([Figure 15](#); note that there are insufficient data to determine NAO-related MLD variations in the subpolar North Atlantic.) This pattern of MLD anomalies is similar to the pattern of SST anomalies associated with the NAO ([Figure 14](#)), with negative MLD anomalies corresponding to positive SST anomalies and vice versa.

Figure 15 Difference in mean winter (December–March) ocean mixed layer depth (m) between years when the NAO index (defined as in the middle panel of [Figure 10](#)) exceeds one standard deviation over 1955–2003. The contour increment is 6 m and positive (negative) differences are given by the solid (dashed) contours.

The SST tripole pattern (Figure 14) has been shown to recur from one winter to the next with little persistence during the intervening summer. The mechanism for this winter-to-winter memory of the SST anomaly tripole is due to the seasonal cycle of MLD through the so-called ‘reemergence mechanism.’ Briefly, the winter NAO creates a tripole pattern of ocean temperature anomalies that extend down to the base of the deep winter mixed layer. These anomalies persist at depth through spring and summer within the stably stratified seasonal thermocline, insulated from the atmosphere by the formation of a shallow mixed layer in response to increasing solar radiation and weakening stirring due to slackened surface winds. Their sequestration ends in the following fall or early winter when the mixed layer deepens again due to the seasonal intensification of the extratropical atmospheric circulation, and the thermal anomalies created the previous winter become re-entrained into the mixed layer, affecting SST. This re-entrainment thus leads to the ‘reemergence’ of the previous winter’s SST anomalies.

The oceanic response to NAO variability is also evident in changes in the distribution and intensity of winter convective activity in the northern North Atlantic. The convective renewal of intermediate and deepwaters in the Labrador Sea and the Greenland–Iceland–Norwegian (GIN) Seas contributes significantly to the production and export of North Atlantic deep-water and, thus, helps to drive the global thermohaline circulation. The intensity of winter convection at these sites is not only characterized by large interannual variability, but also interdecadal variations that appear to be synchronized with variations in the NAO. Deep convection over the Labrador Sea, for instance, was at its weakest and shallowest in the postwar instrumental record during the late 1960s. Since then, Labrador Sea water has become progressively colder and fresher, with intense convective activity to unprecedented ocean depths (>2300 m) in the early 1990s. In contrast, warmer and saltier deepwaters in recent years are the result of suppressed convection in the GIN Seas, whereas tracer evidence suggests that intense convection likely occurred during the late 1960s.

Sea Ice

The leading pattern of variability of winter Arctic sea ice concentrations exhibits a seesaw in ice extent between the Labrador and Greenland Seas. Strong interannual variability is evident in the sea ice changes, as are longer term fluctuations including a trend over the past 30 years of diminishing (increasing) ice concentration during boreal winter east (west) of Greenland. Associated with the sea ice fluctuations are large-scale changes in SLP that closely resembles the NAO.

When the NAO is in its positive index phase, the Labrador Sea ice boundary extends farther south while the Greenland Sea ice boundary is north of its climatological extent (not shown). This is qualitatively consistent with the notion that the atmosphere directly forces the sea ice anomalies, either dynamically via wind-driven ice drift anomalies or thermodynamically through surface air temperature anomalies. The relationship between the NAO index and an index of the North Atlantic ice variations is strong, although it does not hold for all individual winters, illustrating the importance of the regional atmospheric circulation in forcing the extent of sea ice. In general, the

winters over the past decade have witnessed a retreat of the ice edge throughout the Arctic, even during the recent winters of weak NAO-related atmospheric circulation anomalies.

Summary and Challenges

In this article, we have presented a basic review of modal variability over the North Atlantic. We have focused, in particular, on the NAO, as it is the dominant mode of regional climate variability. It is therefore critical to understand the mechanisms that control and affect the NAO and its temporal evolution.

There is ample evidence that most of the atmospheric circulation variability in the form of the NAO arises from the internal, nonlinear dynamics of the extratropical atmosphere. Interactions between the time-mean flow and synoptic-time-scale transient eddies are the central governing dynamical mechanism. As such, the month-to-month and even year-to-year changes in the phase and amplitude of the NAO are largely unpredictable. But that external forces might nudge the atmosphere to assume a high or low NAO index value over a particular month or season is important: even a small amount of predictability could be useful considering the significant impact the NAO exerts on the weather and climate of the NH.

There are a number of different mechanisms that could influence the detailed state of the NAO. Within the atmosphere itself, changes in the rate and location of tropical heating have been shown to be one way to influence the atmospheric circulation over the North Atlantic and, in particular, the NAO. Tropical convection, in turn, is sensitive to the underlying SST distribution, which exhibits much more persistence than SST variability in middle latitudes. This might lead, therefore, to some predictability of the NAO phenomenon. In addition, climate modeling work has shown that the atmospheric response to the re-emerging North Atlantic SST tripole resembles the phase of the NAO that created the SST tripole the previous winter, thereby modestly enhancing the winter-to-winter persistence of the NAO.

Interactions with the lower stratosphere are also important. This mechanism is of interest because it might also explain how changes in atmospheric composition influence the NAO. For example, changes in ozone, GHG concentrations and/or levels of solar output affect the radiative balance of the stratosphere that, in turn, modulates the strength of the winter polar vortex. Given the relatively long timescales of stratospheric circulation variability (anomalies persist for weeks), dynamic coupling between the stratosphere and the troposphere via wave-mean flow interactions could yield a useful level of predictive skill for the wintertime NAO. One example of the possible role of the lower stratosphere in the wintertime NAO involves Eurasian snow cover conditions. Several studies have suggested a mechanism whereby autumnal snow extent over Eurasia influences the winter NAO via dynamical coupling between the stratosphere and troposphere, with above (below) normal October snow extent leading to a negative (positive) phase of the winter NAO.

One of the most urgent challenges is to advance our understanding of the interaction between GHG forcing and the NAO. It now appears as though there may well be a deterministic relationship, which might allow for moderate low-

frequency predictability and thus needs to be studied carefully. Also, while the predictability of seasonal to interannual NAO variability will most likely remain low, some applications may benefit from the fact that this phenomenon leaves long-lasting imprints on surface conditions, in particular over the oceans.

Climate Variability: Seasonal and Interannual Variability

Synopsis

Seasonal variability of climate is principally controlled by changes in the amount of incoming solar radiation hitting different latitudes during Earth's year-long orbit around the Sun. Continents and oceans respond differently to seasonal changes in solar radiation, adding geographical complexity to seasonal variability. Interannual variability in the atmosphere can be organized into very large scale patterns of wind and temperature fluctuations. These patterns are often found to be associated with slow shifts in ocean circulation and temperature. Coupled ocean-atmosphere models have demonstrated increasing skill in simulating and predicting interannual variability.

Introduction

Seasonal variability refers to periodic fluctuations of average temperature, precipitation, and other weather variables resulting directly or indirectly from the annual cycle of incoming solar radiation. The source of seasonal variability is the well-understood annual periodicity of insolation associated with Earth's orbit around the Sun. Seasonal insolation changes directly force temperature fluctuations with periods corresponding to the insolation variability, causing regular 12-month (annual) periodicities in many locations, especially in middle latitudes, and 6-month (semiannual) periodicities in some regions near the equator or the poles. Thermal inertia in the climate system causes the seasonal cycle of temperature to lag somewhat behind the seasonal cycle of insolation, particularly over the oceans. Other climate variables, such as pressure, humidity, and precipitation, vary seasonally as the result of changes in large-scale atmospheric and oceanic circulations that in turn are associated with the seasonal variability of temperature and temperature gradients. Some annually periodic features of the climate system, such as monsoon onset dates, represent abrupt changes in circulation patterns in response to the smoothly varying seasonal insolation cycle. In a few places, notably along the equator across the Pacific Ocean, atmospheric or oceanic circulation systems respond to insolation variability in ways that create seasonal cycles of temperature and precipitation that do not correspond directly to seasonal changes in insolation.

Interannual variability is defined in terms of the year-to-year fluctuations in seasonal (or monthly) averages of temperature, precipitation, or some other climate variable about the average seasonal value determined by a long-term (generally 30-year) climatological record. Interactions between the atmosphere and upper ocean account for considerable interannual variability. Similar interactions between the atmosphere and continental surface anomalies also modulate climate on interannual time scales but probably to a lesser extent. Some forms of intermittent forcing external to the climate system, such as fluctuations of solar brightness or increased aerosol concentrations caused by large volcanic eruptions, also affect the climate system for more than a season and thus contribute to interannual variability.

Seasonal and interannual variability are at the short time scale, or 'short-term,' end of the spectrum of climate variability.

Seasonal and longer fluctuations are considerably slower than typical 'weather' (i.e., much slower than the time scale of growth and decay of individual clouds or synoptic weather systems). The time scales of seasonal and interannual variability are much longer than the deterministic limit of weather prediction determined from chaos theory, which is thought to be several weeks. Therefore, efforts to understand and predict these short-term climate fluctuations must depend on knowledge of persistent or predictable nonatmospheric forcing. The ultimate cause for seasonal variability is well known, but interannual fluctuations can be much more difficult to attribute to individual causes.

Patterns of seasonal and interannual variability of temperature or precipitation are heavily modulated by large-scale atmospheric dynamics. Planetary wave anomalies organize much of the interannual variability into large-scale teleconnection patterns, or zonally symmetric annular modes, which are often defined in terms of pressure or geopotential height anomalies. The existence of fixed geographical patterns of interannual variability provides a means for these fluctuations to be described and monitored in terms of relatively few large-scale indices of the anomalous circulation, and it provides a framework for assessing the potential long-range predictability of interannual fluctuations.

Causes and Magnitude of Seasonal Variability

The seasonal cycle of Earth's atmosphere is a consequence of systematic changes in incoming solar radiation (or 'insolation') associated with Earth's orbit around the Sun. The primary parameter in determining seasons is the tilt of Earth's rotational axis relative to the plane of its orbit, currently about 23.5° . The Northern Hemisphere is tilted toward the Sun during the half-year that is centered on the boreal summer solstice and tilted away from the Sun during the half-year that is centered on the boreal winter solstice. Earth's orbit is nearly circular at the present time, so the small seasonal variation in the distance from the Sun to Earth plays a much smaller role than the tilt in determining the seasons. Very slow changes in the tilt and circularity of Earth's orbit, so-called Milankovitch fluctuations, cause climate changes over millennial time scales, but these orbital characteristics are considered to be essentially fixed for describing seasonal and interannual variability in this article.

The tilt of Earth's rotational axis relative to its solar orbital axis determines the density of insolation impinging on different latitudes, a phenomenon known as 'beam spreading.' The most intense input of solar radiation occurs at the latitude where the Sun is directly overhead at noon local time. On the dates of the spring and autumnal equinoxes, the Sun is overhead at noon on the equator. This latitude shifts northward and southward between 23°27' latitude in either hemisphere as Earth progresses through its annual orbit of the Sun. The northernmost latitude of maximum insolation density, 23°27'N, is denoted the Tropic of Cancer; maximum insolation occurs there on the boreal summer solstice, on or about June 22. The corresponding southern limit of maximum insolation is called the Tropic of Capricorn, where maximum insolation occurs on the austral summer solstice, usually December 22. The band of latitude within 23.5° of the equator is generally denoted the 'tropics.' Insolation density within the tropics, while variable during the year, is generally high year-round, so seasonal variability of temperature is relatively modest compared to that of higher latitudes.

Near Earth's geographic poles, the seasonal variability of insolation is extreme. Earth's tilt means that no direct sunlight at all is received in the core of the winter season poleward of about 66.5°, so seasonal temperature variability is much larger at high latitudes compared to low latitudes. The Arctic and Antarctic circles, at 66°33' in either hemisphere, denote the latitudes in either hemisphere beyond which the sun drops completely below the horizon for at least one day during the winter.

The seasonal variability of insolation is the direct driver of the seasonal variability of temperature, but other factors modify temperature variations. Figure 1 illustrates the magnitude of the seasonal cycle in surface air temperature, expressed here as the annual range of climatological monthly mean temperature during the year. Values generally increase from the equator toward the poles, consistent with the greater seasonal cycle of solar insolation toward the poles. The seasonal cycle of temperature over the world oceans and equatorial continents is generally less than 5°C. Relative maxima are found in

extratropical continental interiors. The largest amplitudes, exceeding 40°C, are found across northern Canada and northeastern Asia, the northernmost continental regions far downwind from the moderating influence of oceans to the west. The seasonal cycle is smaller in amplitude in the Southern Hemisphere relative to the Northern Hemisphere. The phase of the seasonal cycle generally follows the seasonality of insolation, with maximum temperatures lagging the summer solstice of insolation by a few weeks to a few months.

The geographical variability of the amplitude of the seasonal cycle in temperature illustrates the strong thermal buffering effect of the oceans, whose capacity for storing heat (or thermal inertia) is several orders of magnitude greater than the heat capacity of land surfaces on the continents. The difference is due to two characteristics of bodies of water: the specific heat of liquid water is much larger than that of rock or soil, and vertical motions in the upper ocean distribute heat through a much deeper surface layer than occurs on continents. The oceans store huge amounts of heat in summer and release heat to the atmosphere in winter, damping the seasonal cycle of air temperature very considerably. The larger thermal inertia of the oceans relative to the continents also affects the phase of the seasonal cycle: temperatures over the oceans (or over coastal regions, especially along western coasts affected by westerly winds off the ocean) tend to reach their maximum seasonal value somewhat later in the year than at sites in continental interiors.

The seasonal cycle of precipitation is indirectly related to insolation variations via the seasonal variability of atmospheric temperature, and seasonally varying circulation also plays a major role in modulating precipitation. The moisture content of the air, which is strongly controlled by the Clausius–Clapeyron equation such that warmer near-surface temperatures allow for the possibility of larger vapor content, is one factor that leads to a tendency for the warm season to be the rainy season as well across much of the planet. Another factor is the increased instability of an air column that is warmed at the surface, where most of the increased solar insolation in

Figure 1 Annual range of monthly climatological surface temperature (°C) calculated from data for the period 1950–79. The annual range is less than 5°C equatorward of the blue dashed line; ranges of 10, 20, and 30°C are delineated by solid contours; regions where range exceeds 40, 50, and 60°C are shown by red hatching and successively darker shades of solid red. summer is absorbed. More unstable air promotes the formation of updrafts that cause clouds and precipitation.

Thus, the largest precipitation amounts tend to occur in tropical latitudes (Figure 2). But the largest seasonal cycle amplitudes of precipitation also generally occur in the tropics, despite modest insolation and temperature variability in those latitudes. Small seasonal variations of temperature and upward motion in the tropics can generate large seasonal changes in precipitation. Over tropical oceans, the Intertropical Convergence Zone (ITCZ) tends to shift northward and southward, following the maximum latitude of insolation. This progression causes pronounced wet and dry seasons in the tropics, even if the seasonal cycle of surface temperature is modest.

Tropical continents are often characterized by monsoonal climates, with a pronounced summer rainy season. Monsoons are driven by seasonally reversing continent–ocean temperature gradients. In summer, the lower heat capacity of continents raises the surface temperature above that of the ocean, creating a pressure gradient directed from ocean to continent that drives a moist onshore flow. As the ITCZ shifts poleward in the

summer hemisphere following the maximum latitude of insolation, its shift can be greatly enhanced by the presence of a tropical continent, generating the initiation of a summer monsoon circulation anchored over the continent.

The combination of abundant onshore transport of water vapor and conditionally unstable lapse rates over continents leads to a sharp summertime peak in rainfall, especially in regions where convective precipitation is enhanced by orographic lifting. These ingredients – proximity to a warm tropical ocean, strong continental heating in springtime, and large inland mountain ranges – are present in South Asia, where the world’s most intense monsoon circulation takes place and very large summer rainfall amounts occur (Figure 2(a)). In winter, the monsoon circulation reverses as the continent cools relative to the ocean, and the associated continental climate across South Asia is cold and dry (Figure 2(b)). Similar monsoonal seasonal transitions can be seen in Figure 2 in Africa and northern Australia. Monsoonal circulations also occur in southwestern North America and east of the Andes in South America, but these circulations are less pronounced.

The transition to the rainy season in a strongly monsoonal climate is generally quite abrupt, so an onset date can be defined and monitored on an annual basis. This date is typically very important for agriculture, water, and wildfire management and is identifiable in terms of vegetation greenness and other indices of ecosystem function. The monsoon onset date represents a climatological step change in response to smoothly varying insolation forcing and so is an example of a seasonal variation that is forced by the seasonal cycle in insolation modified by nonlinear processes that affect circulation dynamics. In contrast, the end of the rainy season in monsoonal climates tends to be gradual so that the annual demise of a summer monsoon is much more difficult to characterize than monsoon onset.

The seasonal cycle of precipitation over low-latitude oceans is strongly modulated by seasonal shifts in the Hadley Circulation, which maintains its near-equatorial (rising) branch in the summer hemisphere and its subtropical (sinking) branch in the winter hemisphere. Precipitation is strongly suppressed in the vicinity of the sinking branch, particularly near and to the east of the prominent oceanic subtropical highs in the summer season. Thus, in [Figure 2\(a\)](#), there are extensive regions of low precipitation (<100 mm) across the eastern subtropical Pacific and Atlantic Oceans (20–30°N).

Over the extratropical oceans and western continents, the phase of seasonal precipitation variations is the reverse of that of the tropics: winter tends to be the wet season. This is because summertime convective precipitation over these regions is strongly suppressed by subsidence over the summer subtropical highs. The winter season precipitation maximum results from frontal lifting associated with baroclinic wave activity, which is strongest in winter when temperature gradients are larger, especially in the winter ‘storm track’ regions on the poleward flanks of the principal tropospheric jet streams. Storm track-related boreal winter precipitation maxima, exceeding 500 mm in [Figure 2\(b\)](#), are observed over the northeastern Pacific Ocean and south of Greenland in the Atlantic Ocean.

However, indices of wintertime storminess in these regions do not rise and fall sinusoidally like insolation; instead, mid-ocean storminess in middle latitudes of both the Northern and Southern Hemispheres increases early in the winter and then generally goes through a pause in midwinter, a pattern of variability sometimes described as a ‘coreless winter,’ which projects onto the semiannual (twice-yearly) harmonic of the annual cycle. The midwinter pause in storminess seems to be caused by a nonlinear threshold in jet stream dynamics; several possible specific mechanisms have been proposed to explain this phenomenon.

Equatorward of the Tropics of Cancer and Capricorn, the sun moves directly overhead twice per year, as the latitude of maximum insolation shifts northward before the boreal summer solstice, and again as this latitude shifts southward before the austral summer solstice. Therefore, the seasonal cycle of insolation can drive a semiannual seasonal cycle in the tropics. A semiannual cycle is clearly observed over the tropical Indian and western Pacific Oceans.

At polar latitudes, the absence of insolation for a period of time centered on the winter solstice generates an asymmetric seasonal cycle in insolation. In response, very high latitudes experience a coreless winter in temperature, in which the

seasonal cycle of temperature (like insolation) tends to reach a flat minimum for weeks at a time in a climatological average. Summer temperatures near the poles, like insolation fluctuations, tend to rise and fall in a more sinusoidal manner, reaching an identifiable summertime peak.

In a few regions, the seasonal cycles of temperature and precipitation are determined by regional circulation systems, driven indirectly by insolation variations. An important example is the tropical eastern Pacific Ocean, where a ‘cold tongue’ in surface temperature develops right along the equator in the boreal autumn and weakens in springtime. The spatial and seasonal variations of precipitation are closely tied to ocean temperatures near the equator, with surface wind convergence (and hence precipitation) over the warmest water. Thus, spring is relatively warm and rainy, while autumn is colder and less rainy. The special ocean–atmosphere dynamics that create this unusual seasonal cycle are an intrinsic part of the El Niño cycle of interannual variability.

The geographical variations in seasonal cycles described here have been incorporated into numerous climate classification schemes, which are based in part on the amplitude and timing of seasonal fluctuations of temperature and precipitation. Classification systems are often used to relate different climatic zones to observed geographical variations in flora and fauna because plant species (for example) are typically adapted to limited ranges in temperature and precipitation. Once these associations between climate classifications and ecosystem variables are made, then the classifications can be used to characterize ancient climates where fossil evidence for certain plants or animals can be dated. The same climate–ecosystem relationships are used to formulate estimates of the long-term impacts on ecosystems associated with projected future climate changes.

Causes and Magnitude of Interannual Variability

Monthly and seasonal averages of temperature, precipitation, and other climatic variables are not the same year after year, although across most of the planet the amplitude of the seasonal cycle exceeds by far the deviations from seasonal averages that define interannual variability. [Figure 3](#) describes the interannual variability of Northern Hemisphere winter surface air temperature, expressed as the standard deviation of winter seasonal (December through February) averages. Note that this calculation includes all resolvable fluctuations, including any long-term trends or decadal variability that may be present during these three decades. Comparing this plot with [Figure 1](#), it is easy to see that the interannual variations in northern winter temperature are almost everywhere much smaller than the winter–summer seasonal difference in temperature. The largest values of interannual temperature variability occur over the subpolar continents, including maxima exceeding 5 °C in northwest North America and Siberia. Interannual fluctuations over the oceans are much smaller, rarely exceeding 1 °C.

Interannual temperature variability during other seasons is considerably smaller than in the boreal winter. The local interannual standard deviation of boreal summer temperature is generally less than 1 °C even over the continents. The pronounced winter maximum in interannual temperature variability results from two factors. First, planetary waves are most

Figure 3 Interannual standard deviation of seasonal mean boreal winter surface temperature ($^{\circ}\text{C}$) calculated from data for the period 1950–79. Contours indicating 1 and 2°C are shown as solid green and orange; regions where standard deviation exceeds 3°C are hatched red. Adapted from Shea, D., 1986. Climatological Atlas: 1950–1979. Surface Air Temperature, Precipitation, Sea-Level Pressure, and Sea-Surface Temperature. NCAR, Boulder, CO. Technical Note NCAR/TN-269+STR.

pronounced and most variable during this season, so anomalous troughs and ridges are large during this season. Second, temperature gradients are large in the northern winter; in combination with the possibility of large anomalous troughs and ridges, these temperature gradients can support very large seasonal temperature advection anomalies in the boreal winter season.

Interannual variability of precipitation is largest during the seasons and over the regions where seasonal precipitation averages are large. Thus, the variability is generally larger across the continents in summer and over the oceans in winter. In regions of low-average precipitation, however, even small seasonal precipitation deficits can cause profound hardship on water-stressed environments and societies. In the tropics, interannual variability is large and can be comparable to the range of seasonal variations.

Interannual variability derives from several sources, including the following:

- **Limited sampling of weather:** Although 1 month or 1 season is generally longer than the lifetime of an individual synoptic weather system, there are entirely random differences in the average weather from 1 year to the next associated with the limited sampling of weather during 1 month or 1 season. Such ‘weather noise’ is quite pronounced in precipitation statistics in arid climates, where just one or two intense precipitation episodes (or their absence) can significantly affect the average for an entire month or season.
- **Internal atmospheric variability:** The atmosphere contains internal modes of dynamical variability that are considerably longer lived than individual weather systems. A prominent example is the stratospheric quasi-biennial oscillation (QBO) in equatorial zonal winds, which results from upward propagating planetary waves forced randomly from below in the troposphere. Equatorial stratospheric wave dynamics set the time scale of the QBO, rather than the time scale of the forcing from below. Long-lived internal variability is generally less pronounced in the troposphere

relative to synoptic-scale weather fluctuations. However, some long-lived fluctuations (such as ‘blocking ridges,’ which are persistent regions of high pressure that perturb the middle latitude westerly flow) project significantly onto interannual variability.

- **Ocean–atmosphere interactions:** Nonseasonal oceanic variability occurs over time scales longer than atmospheric weather. Large-scale waves on the thermocline propagate across ocean basins over months or even years. Surface temperature perturbations associated with these waves act as short-term climatic forcing for the overlying atmosphere by modifying the fluxes of latent and sensible heat into the atmosphere, thereby modulating near-surface air temperature, pressure, and humidity. These atmospheric anomalies in turn affect the distribution of vertical motion and precipitation so that the atmospheric response to slowly varying ocean surface temperature anomalies extends through the troposphere. Large-scale atmospheric dynamics worldwide are thereby affected by large oceanic temperature anomalies.

In particular, much of the interannual variability across large regions of Earth has been shown to correlate with fluctuations of the coupled ocean–atmosphere system known as the El Niño Southern Oscillation (ENSO). ENSO extrema generally are linked to the seasonal cycle, with the largest equatorial Pacific sea surface temperature anomalies occurring in the boreal autumn and winter seasons, when the cold tongue is normally most pronounced. Extrema in the ENSO cycle include huge pools of anomalous warm (El Niño) or cold (La Niña) surface water, extending along the equator from the South American coast westward to the dateline (fully one-quarter of the circumference of Earth). Such a gigantic anomaly in ocean surface temperatures profoundly affects the large-scale distribution of deep convective precipitation across the Pacific, which in turn perturbs the Hadley Circulation, the subtropical jet stream across the Pacific, and the storm tracks

and planetary waves in the Western Hemisphere. Thus, the atmosphere transmits the effects of equatorial Pacific Ocean surface temperatures across much of the globe.

- **Volcanic eruptions:** Occasional explosive volcanic eruptions inject large quantities of aerosols into the stratosphere. In addition to the profound effects of volcanic plumes on the local climate, which tend to decay quickly once the eruption episode is over, the stratospheric aerosols can remain in circulation for several years after the eruption, and their effects are distributed by the stratospheric circulation across much of the planet. Global cooling is generally observed during the period of time that volcanic aerosol plumes are resident in the stratosphere, although some volcanic aerosols also absorb outgoing longwave radiation and can thereby increase the greenhouse effect and act to warm the surface.
- **Solar fluctuations:** The brightness of the sun is not constant, although on the day-to-day time scale associated with weather, insolation is nearly constant. Therefore, solar brightness changes are not considered as part of a daily weather forecast. From year to year, however, the sun's brightness does change, on the order of 0.1% or less. The sun undergoes a nearly regular cycle of brightness of about 11 years, associated with variations in sunspot numbers, which is pronounced enough to cause measurable 11-year cycles in temperature. The brightness of the sun also varies on longer time scales for reasons that are poorly understood but can affect long-term climate.
- **Persistent land surface anomalies:** Land surface anomalies, such as soil moisture fluctuations, vegetation changes, or interannual variations in snowpack, can have effects on the overlying atmosphere analogous to ocean surface temperature anomalies. As described in this article's discussion of the seasonal cycle, however, the heat storage capacity of land surfaces is much smaller than upper ocean heat storage, so land surface anomalies are thought to play a smaller role than large-scale ocean anomalies in forcing atmospheric interannual variability. Nevertheless, modeling studies have shown that prescribed large-scale anomalies in land surface characteristics can affect climate significantly. In particular, lengthy episodes of drought in the interior of a continent are exacerbated by a positive feedback on the energy and hydrologic cycles from the land surface: lack of rainfall leads to dry soil and sparse vegetation, which in turn causes decreases in evaporation and moist static energy in the atmospheric boundary layer. These deficits in near-surface water vapor and energy tend to suppress convective precipitation in the summer, acting to perpetuate drought.

On longer time scales, seasonal and interannual variability may be loosely distinguished from longer time scale (decadal–centennial) fluctuations by the relative importance of the climatic processes involved. In particular, a considerable fraction of the forcing for seasonal and interannual variability can be described by focusing on the upper ocean (above the thermocline). The atmospheric interannual variability associated with continental land surface anomalies is not well understood but is generally thought to be less important than oceanic

forcing because the heat capacity of land surfaces is so much smaller. Explosive volcanic eruptions can affect global climate strongly for a year or two following the eruption, after which most aerosols drop out of the stratosphere. A succession of explosive eruptions would be required to strongly affect the climate for a longer period of time. The abyssal oceanic circulation, including the thermohaline circulation, may play a much more prominent role at longer (decade–century) time scales. The same is true for solar brightness fluctuations. Long-term changes in vegetation patterns, and the relatively slow changes in atmospheric composition, are very important on decade–century time scales but may also modulate interannual variability.

Diagnosis and Prediction of Interannual Variability

Interannual variability does not occur randomly across the planet. Preferred large-scale patterns of circulation anomalies, called teleconnection patterns, have been identified via statistical analysis of the observed interannual variability of sea level pressure, zonal wind, or geopotential heights. These teleconnection patterns tend to be most pronounced in the boreal winter season when planetary wave energy is maximized. The existence of such patterns allows climatologists to describe a large fraction of interannual variability using just a few indices of the anomalous circulation associated with teleconnection patterns. The existence of such patterns was recognized early in the twentieth century by visionary climate data analysts such as Sir Gilbert Walker, but the causes of the patterns and their potential predictability have been the subject of very active recent research.

Among the most prominent teleconnection patterns are the Southern Oscillation over the tropical Pacific (now known to be associated with the equatorial ocean surface temperature anomalies of El Niño), the North Atlantic Oscillation (NAO) of heights and temperatures, and the Pacific–North American pattern of geopotential heights, each of which was recognized by Walker in the 1920s. Seasonal surface temperature and precipitation anomalies are associated with the planetary wave perturbations that characterize these patterns. In the Southern Hemisphere, geopotential heights are observed to vary in a characteristic wavenumber-3 pattern anchored to the distribution of continents and oceans in middle latitudes.

Another class of teleconnection patterns, the zonally symmetric ‘annular modes,’ was also recognized decades ago. Analysis of new global data sets has reconfirmed the utility of a zonally symmetric description of interannual variability, so these modes have been the subject of renewed research in recent years. Annular modes can be identified as fluctuations in the zonally averaged zonal wind in the extratropics of either hemisphere. Alternatively, via the geostrophic wind relationship, annular modes appear as fluctuations in the north–south gradient of geopotential height between the extratropics (around 45° latitude) and high latitudes (around 80°) in either hemisphere.

Various names have been given to these modes of variability over the years. Fluctuations in zonal wind averaged around latitude circles were referred to as the ‘index cycle’ in the

mid-twentieth century. More recently, modes of variability describing much of the same variance have been called the Arctic and Antarctic Oscillation, or the Northern and Southern Annular Modes.

The Northern Annular Mode (NAM) and the NAO present different conceptual paradigms but describe similar sets of interannual surface temperature and precipitation anomalies in the extratropics. Defined as an annular mode, the NAM and its Southern Hemisphere counterpart exhibit pronounced coherent structure extending up into the stratosphere. The NAO, defined early on in terms of surface temperature variability, has naturally been diagnosed in terms of ocean–atmosphere interaction. But using either paradigm, studies of the possible cause of this general package of variability have suggested that interannual fluctuations of the NAM and NAO are probably manifestations of internal atmospheric variability, rather than forced by external causes that could be predictable in advance. Thus, at the present level of understanding, interannual variability associated with the NAM and NAO could serve to limit the overall predictability of interannual variability in extra-tropical latitudes.

Drought episodes, defined as prolonged periods of unusually dry weather, are another form of interannual variability with profound consequences for ecosystems and for people. Droughts are usually defined over continental regions, and they can be characterized in terms of time scale or, in a complementary way, in terms of the impacts of prolonged precipitation deficits on different components of the land–atmosphere system. Thus, ‘meteorological drought’ is a deficit of precipitation from a long-term average, and it can be defined for either a short period (days to weeks) or a much longer period (decades). Prolonged meteorological drought can affect vegetation, crops, and soil moisture (‘agricultural drought’), and stream flows and lake levels (‘hydrological drought’).

Similar to other aspects of interannual variability related to teleconnection patterns, persistent anomalies in ocean surface temperatures have been examined to explain the possible cause of atmospheric circulation changes that can cause long-term drought. North American droughts have been diagnosed in this way, with multiyear episodes of cold equatorial Pacific Ocean temperature anomalies identified as potentially causing severe North American drought. Other tropical ocean temperature anomaly patterns seem to contribute to atmospheric circulation changes conducive to long-term drought as well.

In order to monitor interannual variability, the major weather services of the world calculate monthly and seasonal averages of temperature, precipitation, and geopotential height at the end of each month. Indices of the principal teleconnection patterns and ocean temperatures in the tropical Pacific are a particular focus of real-time monitoring. Drought indices, which can be based on different combinations of precipitation, soil moisture, and vegetation status indicators, are particularly closely monitored and disseminated to the public. Areas of the planet experiencing extreme, persistent anomalies of temperature and precipitation are also monitored closely.

If any of the causes of interannual variability listed here persist longer than a season (or if the causes themselves could

be predicted a season or more in advance), and if the magnitude of interannual variability forced thereby is large compared to unpredictable interannual variability such as weather noise, then in principle it should be possible to make skillful predictions of interannual variability at lead times extending beyond the deterministic limit of a weather forecast. Such seasonal forecasts of short-term climate anomalies cannot predict the evolution of individual weather systems and thus are incapable of predicting the weather on specific days. The goal instead is to forecast how the average weather for a month or a season will differ from the expected value derived from a straightforward climatological average.

Seasonal hurricane forecasts for the northwest Atlantic region, for example, are based on knowledge of the ENSO cycle, Atlantic Ocean temperature anomalies, the phase of the QBO in tropical stratospheric winds, and several other factors that can be observed prior to the start of the hurricane season. At the beginning of the North Atlantic hurricane season (in late summer), forecasts are issued for the number of tropical cyclones that are expected to make landfall in North America based on historical associations between the factors listed here and subsequent hurricane activity. It should be emphasized that no attempt is made to forecast the timing or tracks of individual cyclones, just the aggregate hurricane activity for the entire season.

Interannual variability of step changes in the seasonal cycle, such as an early or late monsoon onset date, can also potentially be predicted based on antecedent forcing. The ENSO cycle, for example, has been shown to have a statistical relationship with onset dates for the summer monsoon in South Asia and southwestern North America. Improving forecast skill for such step changes has proven to be a difficult challenge, at least in part because step changes occur on the fast time scale of weather.

Active operational prediction efforts are aimed at producing skillful and useful estimates of the probabilities of seasonal climate anomalies of temperature and precipitation up to about a year in advance. At present, the principal well-demonstrated source of seasonal climate predictability is the ENSO cycle, which has been shown to correlate with seasonal climate anomalies in many regions throughout the world. Ocean temperatures and surface winds across the tropical Pacific are now observable in real time thanks to the development of an extensive monitoring system that combines in situ and satellite observations. Climate forecasters know that if the equatorial Pacific Ocean and atmosphere develop a significant cold or warm anomaly in the boreal autumn, then it is highly likely that such anomalous conditions will persist through the following winter season. Empirical prediction techniques, based largely on the historical occurrence of systematic seasonal anomalies of temperature or precipitation in previous ENSO-extreme winters, have demonstrated useful skill. More recently, dynamical models driven by ENSO-related ocean temperature anomalies have also demonstrated seasonal prediction skill. The development of ENSO-based seasonal forecast skill using dynamical models has raised optimism that other sources of potential predictability on the seasonal time scale could be explored and exploited using models.

Energy Balance Climate Models

Synopsis

Energy balance climate models are a class of simplified models of the large-scale climate based upon the energy balance of a column of air/ocean above/below an infinitesimal box at the surface. When integrated over the entire surface area they are the global average models. Zonal average models can be constructed by integrating around latitude circles. Some of the more simplified models can be solved analytically providing special insights to such aspects of climate at its sensitivity to small perturbations of solar brightness or greenhouse gases.

Introduction

Climate models come in a variety of sizes and degrees of complexity. The global energy balance models are at the simplest level of description of the global climate system. These models represent the entire climate system with a single number, the global average temperature. The coupled ocean/atmosphere general circulation models that incorporate the detailed circulation of the atmosphere and the oceans as well as other components, altogether employing millions of numbers to specify the state of the climate, are at the other end of the spectrum of models. The purpose of these models is to gain a better understanding of the climate system, why its current state is what it is, how sensitive it is to external perturbations, and how it compares to the observations in detail. This article considers the models at the very low end of the so-called hierarchy of climate models, the energy balance climate models (EBCMs). Most of these models use the surface temperature field of the Earth as the basic indicator of the climate. The physical principle that constrains or determines this climate is the rate of incoming solar radiation absorbed by a column of air over a particular small box at the surface being balanced by the rate of release of radiation to space from the same column added to the net flux of heat leaving the column to enter surrounding columns. The article will introduce the global models, then proceed to models with latitude dependence and finally to both latitude and longitude dependence.

Globally Averaged EBCMs

The surface of a material body emits electromagnetic radiation proportionally to the fourth power of the Kelvin temperature. The radiation is bunched in wavelengths peaked at a value inversely proportional to the wavelength. This peak is in the visible part of the spectrum (~ 500 nm) for the Sun's radiation and in the infrared (~ 15 μ m) for the Earth's radiation. Over the range of values important to climate, the infrared radiation energy flux (Watts per meter squared = W m^{-2}) can be written approximately as

$$I_0(T) = A_0 + B_0 T \quad [1]$$

where $A_0 = 314.9 \text{ W m}^{-2}$ and $B_0 = 4.61 \text{ W m}^{-2} (\text{°C})^{-1}$ and T is the surface temperature in degrees Celsius. If the Earth had no

atmosphere, the planet would radiate the amount given by the formula for each square meter of surface area (on global averaging). The Sun supplies energy mostly in the visible range such that a square meter receives energy per second perpendicular to the rays from the Sun of about $S_0 \approx 1360.8 \pm 0.5 \text{ W m}^{-2}$ (Kopp and Lean, 2011). The balance of rates can be written as

$$4\pi R^2(A_0 + B_0 T) = \pi R^2 S_0 a_p \quad [2]$$

where R is the radius of the Earth (which along with π cancel out) and a_p is the fraction of sunlight absorbed from space by the Earth system (the planetary co-albedo) – its current value is taken to be 0.70. Inserting the numerical values, it can be computed that $T = -16.7 \text{ °C}$, a value over 30 °C too cold (given the present co-albedo). Satellite data can be used to get estimates of the coefficients (Graves et al., 1993) in the formula for $I(T)$ by using the data from different locations and seasons for T . The approximate results are $A = 206 \text{ W m}^{-2}$ and $B = 2.2 \text{ W m}^{-2} (\text{°C})^{-1}$ (actually, these values are slightly uncertain because of the differences in their values for clear sky versus cloudy skies; values that are consistent with the correct temperature for the global average and within the range of error for the observations are chosen). Using these empirical coefficients yields $T = 14.5 \text{ °C}$, a value very close to that observed. The atmosphere contains gases that absorb in the infrared range then reradiate at colder temperatures at roughly 5 km above the ground. This so-called greenhouse effect is the reason for the warmer planetary surface. Next one can ask how much the temperature would change if the Sun's output were to increase by 1%. The answer is approximately 1.08 °C , which can be calculated by incrementing eqn [2]. The next question is: How much does the equilibrium temperature change if the CO_2 concentration is doubled? This was estimated from the reduction of outgoing radiation caused by such an action. The change in radiation balance at the top of the atmosphere is about 4.0 W m^{-2} (Myhre et al., 1998), based on accurate radiative transfer calculations. Inserting the negative of this value on the right-hand side of eqn [2] gives an increase of T by 1.82 °C . This latter number gives the sensitivity of the global average temperature to a doubling of CO_2 for the global average EBCMs when the empirical formula for $I(T)$ is used, and it is assumed that there are no changes in the planetary albedo during the doubling experiment. By the way, if there were no atmosphere (A_0 and B_0 apply) then the sensitivity to

raising the solar constant by 1% leads to only half the sensitivity as in the current atmosphere. Evidently, the presence of the atmosphere and its effect on outgoing radiation amplifies the sensitivity by about a factor of 2. This increase of sensitivity is due to the feedbacks in the atmospheric system – most of the effect coming from water vapor increases as the planet is warmed, since water vapor itself is a greenhouse gas and hence the strong positive feedback. The water vapor feedback mechanism along with some others such as the so-called lapse rate feedback are thought to be captured in the coefficient B . There can be other feedbacks in the climate system not included in the simple balance that is used, and the nature of these additional feedbacks is a very active research area in climate dynamics. Coupled ocean/atmosphere general circulation models yield a range of sensitivities for doubling CO_2 centered at 3.0 ± 1.0 °C.

One-Dimensional EBCMs

One-dimensional EBCMs were introduced by [Budyko \(1968\)](#) and [Sellers \(1969\)](#). In this case, the zonal averages are considered (averages around latitude belts), equivalently, and it was imagined that the planet to be zonally symmetric. Sunlight is not distributed evenly from one latitude belt to another: more solar energy per unit area strikes the tropics than the polar areas. If the seasonal distributions are averaged out as well an approximate formula can be obtained for the normalized distribution of sunlight as a function of latitude:

$$S(x) = 1 + S_2 P_2(x); \quad \text{where} \quad P_2(x) = \frac{1}{2}(3x^2 - 1); \quad [3]$$

$$\int_0^1 S(x) dx = 1$$

where x is the sine of latitude (or cosine of the polar angle θ), which varies from 0 at the equator to unity at the North Pole, $S_2 = -0.482$, and $P_2(x)$ is the second Legendre polynomial. One advantage of using x as the measure of latitude is that equal increments of x contain equal areas around a latitude belt on the sphere. For a given latitude belt dx , there will be an absorbed incoming flux of sunlight (letting $Q \equiv S_0/4$) equal to $Qa(x)$, where $a(x)$ is the absorptivity (or co-albedo) of the Earth-atmosphere system at sine of latitude x ; the outgoing infrared radiation from the belt may be written as $A + BT(x)$. To close the budget, the net rate of heat that flows into/from the belt per unit area from/into belts on either side needs to be considered.

Satellite observations show ([Graves et al., 1993](#)) that the co-albedo $a(x)$ decreases with latitude because of the zenith angle effect (solar rays from near the horizon tend to be reflected more by the Earth-atmosphere system). The empirical result is

$$a(x) = a_0 + a_2 P_2(x) \quad [4]$$

with $a_0 = 0.679$ and $a_2 = -0.241$ ([Graves et al., 1993](#)). The product of $S(x)$ and $a(x)$ leads to

$$S(x)a(x) \approx 0.702 - 0.535 P_2(x) + \dots \quad [5]$$

after truncating the Legendre polynomial series at the second degree (neglecting a small $P_4(x)$ term that results from the product of the two $P_2(x)$ terms).

The simple model is adopted where the heat flux is proportional to the negative gradient of the temperature field. In spherical coordinates, this can be expressed as

$$\begin{aligned} \text{poleward heat flux} \equiv F_\theta &= -D \frac{1}{R} \frac{\partial T}{\partial \theta} = -D \frac{1}{R} \frac{\partial T}{\partial x} \frac{\partial x}{\partial \theta} \\ &= -D \frac{1}{R} \sqrt{1-x^2} \frac{dT}{dx} \end{aligned} \quad [6]$$

where θ is the polar angle and R is the Earth's radius. The heat lost per unit area in the thin belt is the divergence taken in spherical coordinates, $\frac{1}{R \cos \theta} \frac{\partial \cos \theta F_\theta}{\partial \theta}$. The two factors of R can be absorbed into the definition of D or what is equivalent, setting R to unity.

With this parameterization, the energy balance equation becomes:

$$-\frac{d}{dx} \left(D(1-x^2) \frac{dT}{dx} \right) T + A + BT = Q((Sa)_0 + (Sa)_2 P_2(x)) \quad [7]$$

with $(Sa)_0 = 0.702$, $(Sa)_2 = -0.535$. In general D , A , and B might depend on x and in more complicated models they might depend on $T(x)$ itself. In the case where these phenomenological coefficients are constant, the two-mode solution is the exact solution. By this, it was meant that

$$T(x) = T_0 + T_2 P_2(x); \quad T_0 = \frac{Q(Sa)_0 - A}{B}; \quad T_2 = \frac{Q(Sa)_2}{B + 6D} \quad [8]$$

is the exact solution. Using the observed values $T_0 = 14.5$ °C and $T_2 = -28.0$ °C, one can solve to find that a better value of A is 206 W m^{-2} and $D = 0.724 \text{ W m}^{-2} (\text{°C})^{-1}$. [Figure 1](#) shows that the parabolic fit in x is excellent except near the equator where diffusive heat transport is a poor approximation. [Figure 2](#) shows the total heat flux toward the North Pole as a function of x :

$$\begin{aligned} [\text{total heat flux crossing latitude circle at } x] \\ = -6\pi T_2 D R^2 x(1-x^2) \end{aligned} \quad [9]$$

[Figure 2](#) also shows points from observations for the year 1988 ([Trenberth and Solomon, 1994](#)). The significance of [Figures 1 and 2](#) is that even though there is some arbitrariness in the parameters, the EBCM captures the shape of the curves almost exactly (quadratic in [Figure 1](#) and $x(1-x^2)$ in [Figure 2](#)).

Time Dependence

The EBCM can include time dependence by introducing a heat storage term into the energy balance. Here the problem is complicated by the fact that the effective heat capacity over land area is surely very different from that over ocean surfaces. Consider first the case of a uniform planet with an effective heat capacity per unit area of C . Also stick to the uniform zonal average. The energy balance can be written as

$$\begin{aligned} C \frac{\partial T'}{\partial t} - D \frac{d}{dx} \left((1-x^2) \frac{dT'}{dx} \right) T' + BT' &= F(x, t) \\ &= F_0(t) + F_2(t) P_2(x) \end{aligned} \quad [10]$$

Figure 1 Temperature ($^{\circ}\text{C}$) versus the $x = \sin(\text{latitude})$ (equator is 0, pole is 1). The solid line is the model fit with parameters $S = 1360 \text{ W m}^{-2}$, $A = 206 \text{ W m}^{-2}$, $B = 2.20 \text{ W m}^{-2} (^{\circ}\text{C})^{-1}$, and $D = 0.72 \text{ W m}^{-2}$.

Figure 2 Heat flux across a latitude circle at $x = \sin(\text{latitude})$ toward the pole in petawatts (10^{15} W).

where $T'(x, t)$ is the departure from the steady-state solution of the last section, and $F(x, t)$ is a space-time-dependent 'forcing' containing only x dependence up to two Legendre modes.

If $F(x, t)$ is set suddenly to 0, there is an exponential decay to the steady-state solution in each Legendre mode with time constants $\tau_0 = C/B$ and $\tau_2 = \tau_0 / \left(1 + 6 \frac{D}{B}\right)$. If the planet is all land, the effective heat capacity might be taken to be that of about half the mass of the atmosphere, leading to a decay time of about a month for the global average (T'_0), a value reminiscent of the results from detailed radiative convective models (Manabe and Strickler, 1964), and about 9 days for T'_2 . If the planet is all ocean, the mixed layer of the ocean should be used

for the heat capacity. This leads to a global decay time of a few years. For long-time scales, the deeper ocean has to be taken into account, leading to much longer adjustment times.

Further Extensions and Applications

In this short introduction to EBCMs, only its simplest linear members have been introduced in an effort to show how these models can be used to develop intuition about the real climate system. The above treatment can be extended to two dimensions (2D) on the globe but must take into account the geography in the $C(\hat{r})$ (large over ocean, small over land) term where $\hat{r}$ denotes the location on the Earth's surface. This can be

done, but the solutions require numerical methods and the storage capabilities of a modern computer. The most important application of the 2D case is to the seasonal cycle. The 2D EBCM captures the geographical morphology of the surface thermal field of the seasonal cycle with remarkable fidelity because the amplitude and phase of the field are dominated by the contrasting effective heat capacities of the two surfaces (North et al., 1983).

Another important application is to the larger scale response to the small-scale drumming of weather fluctuations which in this model are represented as white noise in space and time for the driving term $F(\hat{r}, t)$ (Kim and North, 1991). Once again, the geographical pattern of climate variability is faithfully represented even in different frequency bands from months to decades. The 2D EBCMs have proven useful in a number of paleoclimate applications. Two-dimensional models have also been used in the detection and attribution of faint climate signals. These and many other examples can be found in publications by the authors.

Nonlinear terms can be included in the EBCM. For example, the co-albedo can be modified to include the ice-albedo feedback mechanism. One way this can be accomplished is by allowing an ice or snow line to be tied to a particular critical temperature. Budyko (1968) suggested that if the mean annual temperature is below -10°C , then there will be perennial ice poleward of this latitude with its smaller co-albedo. One can also tie the seasonal snow line to the freezing point. One might also employ nonlinear infrared radiation effects as well as in the horizontal transport of heat. The ice-albedo effect has been most interesting in that the nonlinearity induces more than one solution for a given set of conditions such as a particular value of the solar constant. These model solutions can feature jumps from one branch of the solution to another for a continuous change in internal parameters (North et al., 1981).

EBCMs can also be attached to one (vertical)-dimensional ocean models. One example is the upwelling-diffusion ocean model which for global average has been used by Wigley and Raper (2002) and in two horizontal dimensions by Kim et al. (1992) in transient climate scenarios.

Global Impacts of the Madden–Julian Oscillation

C Zhang, University of Miami, Miami, FL, USA

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

As its convection center moves from the Indian Ocean to the Pacific Ocean, the Madden–Julian Oscillation affects global weather, climate, and many other phenomena in the Earth system.

Introduction

The Madden–Julian Oscillation (MJO) affects global weather and climate mainly through two mechanisms. One is direct by enhancing or suppressing tropical convection and rainfall along its propagation pathway from the Indian Ocean to the Pacific Ocean. The other is indirect by generating atmospheric or oceanic wave disturbances that propagate into regions with little or no direct signals of the MJO itself. MJO's influences on weather and climate are not separated from each other. The degree to which global weather is affected by the MJO often depends on the phases of certain climate modes. Climate phenomena under the influence of the MJO in turn modulate weather events in many regions of the world. In addition, the MJO also affects many important and interesting phenomena in the atmosphere and ocean that are not commonly categorized as either weather or climate. Because of the large number of weather, climate, and other phenomena in the Earth system under the influence of the MJO, only very brief descriptions of them are possible here. The listed further reading materials provide more detailed discussion of the global impact of the MJO.

Severe Weather

Severe weather around the world occurs with or without the MJO. However, the strength, frequency, and spatial and temporal distributions of severe weather can be affected by the MJO. More precisely, these characteristics of severe weather may change depending on the location of the MJO convection center and periods with and without active MJO events.

Tropical Cyclones

Effects of the MJO on Tropical Cyclone (TC) frequency can be visualized from [Figure 1](#), which shows TC tracks and rainfall anomalies in the global tropics at four typical stages of the MJO. The density of the tracks illustrates the TC frequencies. They vary with the longitudinal location of the MJO convection center. Over the southern Indian Ocean, TC frequency is highest when MJO convection center is over the Indian Ocean, but lowest when it is in the Western Hemisphere. Over the Bay of Bengal, TCs are the most frequent when the MJO convection center is over the Maritime Continent, and the least frequent when the MJO convection center is in the Western Hemisphere. Over both the northwestern and southwestern Pacific and

north of Australia, TCs are the most (least) frequent when the MJO convection center is over the western Pacific (Indian Ocean). TCs (hurricanes) over the northeastern Pacific occur most frequently when the MJO convection center is in the Western Hemisphere, and least frequently when the MJO convection center is over the Maritime Continent. Atlantic hurricanes are the most (least) frequent when the MJO convection center is over the Indian Ocean (western Pacific). The MJO may affect TCs through impacts on local vertical wind shear, low-level convergence, midlevel moisture, cyclonic relative vorticity, deep convection, small eddies, and synoptic disturbances serving as embryos for TCs.

Tornados

In boreal spring (March, April, and May), the contiguous US is prone to tornados. Violent tornado outbreaks days, with six or more strong tornados within a 24-h period, are more than twice as frequent when the MJO convection center is over the Indian Ocean than other times. Combined intraseasonal anomalous patterns (an upper tropospheric trough extending eastward from the Western United States, upper tropospheric southwesterly wind anomalies, and low-level southerly wind anomalies over the southern Great Plains) and the seasonal circulation (a ridge over the Southeastern US) provide atmospheric conditions favorable for violent tornado formation.

Extreme Rainfall

Globally, frequencies of extreme rainfall events during periods of the active MJO are about 40% higher than periods of weak or no MJOs. Extreme rainfall events are defined here as record-breaking rain events or total rain amount within a given top percentile of the local climate rainfall probability distribution. While several events that brought tremendous damages to society have been suspected to occur partially because of the MJO, the most convincing evidence of MJO modulation on extreme rainfall is the change of extreme rainfall frequency as a function of the longitudinal location of the MJO convection center. For example, during March–May in the equatorial east Africa, 62% of extreme rainfall events over the highlands occur when MJO convection is over the Indian Ocean, while 72% of extreme events over the coastal region occur when MJO convection is suppressed over the Indian Ocean and Maritime Continent. Extreme rainfall events in the semiarid north-central coastal area of Chile occur normally only 3–5 times during the fall and winter of rainy years; about 80% of them happen when

Figure 1 Tropical cyclone (TC) tracks (1975–2011) and precipitation anomalies (1998–2011) when MJO convection center is over the (a) Indian Ocean, (b) Maritime Continent, (c) western Pacific, and (d) Americas and Africa. an MJO convection center is in the central equatorial Pacific. In boreal winter over the contiguous United States, extreme rainfall (exceeding 90th percentile of frequency distribution in intensity and spatial coverage) occurs twice as frequently during a period with an active MJO than one without, and is the most frequent when the MJO convection center is over the Indian Ocean.

Flood

It has been suggested that some unusual flood events with large casualties were associated with particular MJO events. However, as for extreme rainfall events, the most evident effect

of the MJO on floods comes from fluctuations of the flood frequency through the life cycle of the MJO or between periods with and without active MJO events. Take 'large flood events' as an example, which is defined as extreme flood events with damages that have been reported with intervals of a decade or longer. Their probability or occurrence frequency is measured as the total number of flood days or flood events (which consists of continuous flood days) divided by the total number of days in a given MJO phase. Frequencies of large flood events in many parts of the world are modulated by the MJO (Figure 2). When the MJO convection center is over the western Pacific, large flood events are most frequent along the west coast of North America, on the Philippine Islands, and over

Figure 2 Locations of large flood during 1985–2010 based on the Dartmouth Flood Observatory Global Archive of Large Flood Events at University of Colorado (Brakenridge, G.R. Global Active Archive of Large Flood Events. Dartmouth Flood Observatory at University of Colorado, <http://floodobservatory.colorado.edu/Archives/index.html>). Red boxes mark regions where probabilities of total flood days and/or events are significantly affected by the MJO. Zhang, C., 2013. Madden-Julian oscillation: bridging weather and climate. *Bulletin of the American Meteorological Society* 94, 1849–1870.

South Asia and West Africa. They are the least frequent in these regions when the MJO convection center is over the Indian Ocean. In contrast, large flood events in Central America and East Africa are the most (least) frequent when the MJO convection center is over the Indian Ocean (western Pacific). Over China, frequencies of large flood events tend to be reduced during periods with strong MJO activities in comparison to those without. Similar MJO effects on large flood events can be found in other regions (Australia, the Maritime Continent, the Middle East, Southern Africa, the Andes).

Lightning

By affecting characteristics of deep convection, the MJO modulates the global lightning frequency. In the main region of MJO activity, namely, the tropical Indian and Pacific oceans, very deep (>10 km) lightning-producing convective towers tend to occur immediately prior to the local onset of MJO convective periods, yielding the highest lightning frequency. The MJO also affects lightning outside the tropics. For example, as the MJO convection center moves from the Indian Ocean to the Pacific Ocean, summertime lightning over the United States exhibits a migrating pattern clockwise starting from the Southeast. The MJO effects on lightning project on to the Schumann resonances (SR), which are electromagnetic waves of zonal wave number one in the natural cavity between the Earth and the ionosphere. The intensity of the SR is mainly modulated by fluctuations in the number and intensity of global lightning activity. Intraseasonal perturbations in the SR have been detected and related to the MJO.

Fire

Through its modulation on rainfall and perhaps also wind and temperature, the MJO affects the frequency of wildfire in many regions of the world. Global monthly fire counts are always larger when there are active MJO events than otherwise. **Figure 3** compares global fire frequencies at two stages of the MJO life cycle: one is when MJO convection begins over the

Indian Ocean ('initiation stage'), the other is when MJO convection has propagated across the Maritime Continent and reached the western Pacific ('WP stage'). Fire frequencies are much higher at the MJO initiation stage than the WP stage over the Amazon and northern Australia, whereas they are lower over Alaska and north of Lake Victoria over equatorial Africa. Over East Europe and European Russia, fire is more concentrated to the south at the MJO initiation stage but spreads to the north when the MJO becomes mature. Other regions experience their fire maxima and minima at different MJO stages (phases). Over Siberia, fire is frequent when MJO convection is most enhanced over the eastern Indian Ocean.

Cold Surges

Two-thirds of extreme cold surges with temperature reductions greater than 2 standard deviations in East Asia occur when the MJO convection center is over the Indian Ocean. Although in general, the MJO tends to prevent weak cold surges from penetrating southward into the subtropics and tropics, an MJO event with its convection center stalled over Sumatra resulted in an extreme cold event during a cold year of El Niño Southern Oscillation (ENSO) (February 2008) that broke a 50-year record of minimum daily temperature and duration of large negative temperature anomalies over Southeast Asia. An extreme cold surge with record-breaking snowfall in Korea in the winter of 2009–10 might have resulted from combined effects by the MJO and the Arctic Oscillation (AO).

Climate

Climate phenomena subject to MJO influences include the monsoons and several climate modes such as ENSO, the North Atlantic Oscillation (NAO), the AO and Antarctic Oscillation (AAO), the Pacific North American (PNA) pattern, and the Indian Ocean Dipole (IOD). While these climate modes all feed back to the MJO, discussions in this section focus on MJO effects on them.

Figure 3 Fire frequency (%) in each $1^\circ \times 1^\circ$ grid box at the (a) MJO initiation stage (MJO convection starts over the Indian Ocean) and (b) MJO WP stage (MJO convection center is over the western Pacific). The fire count data are from the Along Track Scanning Radiometers (ATSR) World Fire Atlas (<http://due.esrin.esa.int/wfa/>).

Monsoons

The MJO is the main source of intraseasonal fluctuations in many, if not all, monsoon systems. About 33–80% of intra-seasonal variability of monsoon rainfall is related to the MJO. Summer monsoon onsets and breaks are often related to the MJO, especially for the Indian and Australian monsoons. Convectively active episodes of the MJO can enhance heavy rainfall events during summer monsoons. The northward propagation of the MJO in boreal summer is as important as its eastward propagation to the Asian monsoon. The MJO affects the American monsoons through two mechanisms: MJO perturbations propagating eastward along the Pacific Inter Tropical Convergence Zone (ITCZ), and Rossby wave trains excited by MJO convection in the tropical Indo-Pacific region that enter South America. Both westward propagating equatorial Rossby waves excited by MJO convection over the Indian Ocean and eastward propagating equatorial Kelvin waves excited over the tropical Atlantic Ocean are considered the main mechanisms for the MJO to affect the African monsoon.

El Niño Southern Oscillation

Strong episodes of the MJO often occur prior to major ENSO warming events (El Niño). The peak of ENSO

warming in the eastern Pacific in boreal winter is usually preceded by enhanced MJO activities in boreal spring. This leads to a significant correlation between ENSO sea surface temperature (SST) and MJO activities with the former lagging the latter by 6–10 months. Oceanic downwelling Kelvin waves forced by westerly wind anomalies of the MJO are the main mechanism for the MJO to influence ENSO. In an ENSO paradigm, the MJO acts as a main source of high-frequency stochastic forcing that drives ENSO. Meanwhile, feedback from ENSO SST to the MJO can be important to this MJO–ENSO connection, making the MJO a ‘multiplicative’ stochastic forcing of ENSO.

North Atlantic Oscillation

Enhanced (suppressed) MJO convection over the central Pacific can considerably amplify the NAO in its negative (positive) phase. Northward momentum transport by Rossby wave dispersion from the tropical Pacific to the extratropical North Atlantic is thought to be the main mechanism for the MJO influence on the NAO. The daily phase of the wintertime NAO can be predicted with a success rate of about 70% at a lead time of 9–13 days by a statistical model based on the connection between the MJO and NAO.

Arctic Oscillation

During winter, the positive (negative) phase of the AO, also known as the Northern Annular Mode (NAM), is twice as likely to occur as the opposite phase when MJO convection is enhanced (suppressed) over the Indian Ocean. When MJO convection is enhanced (suppressed) in the Eastern Hemisphere, especially over the Maritime Continent, the number of days of positive (negative) AO phase becomes large. In November–March, 18–21% of the variance in extratropical 1000-hPa geopotential height is related to the MJO. The MJO influence on the AO is also through Rossby wave trains excited by MJO convection and propagating from the tropical Pacific into the extratropics.

Antarctic Oscillation

The southern hemispheric counterparts of the NAM and AO are the Southern Annular Mode (SAM) and AAO. They are also influenced by the MJO. Negative (positive) phases of the AAO in austral winter tend to occur when MJO convection is enhanced (suppressed) over the central Pacific. The SAM reaches its maximum positive phase immediately after MJO convection peaks over the equatorial Indian Ocean. The Antarctic circumpolar transport can be accelerated by MJO-enhanced surface westerly wind associated with the SAM that covers almost the entire latitude circle at 60° S.

PNA Pattern

The PNA teleconnection pattern undergoes both interannual and intraseasonal variations. On the intraseasonal timescale, about 30% of the emergence of the PNA pattern is related to the MJO. The positive (negative) phase of the PNA pattern is most likely to occur when MJO convection is inactive (active) over the region from the Bay of Bengal to the western Pacific. This MJO–PNA connection explains about 30% of the emergence of the PNA pattern. This MJO–PNA connection is through propagation of Rossby wave trains from anomalous convection of the MJO.

Indian Ocean Dipole

Anomalous upwelling oceanic Kelvin waves forced by easterly anomalies associated with suppressed convection of the MJO over the equatorial Indian Ocean can lead to shoaling of the thermocline in the eastern Indian Ocean and thereby help the onset of positive phases of the IOD. Active convection associated with the MJO may help terminate a positive IOD phase by generating downwelling oceanic Kelvin waves that tend to deepen the thermocline. By the same token, an IOD mature phase can sustain itself only in the absence of strong MJO events.

Upper Ocean

Through its anomalies in surface wind, cloudiness, and rainfall, the MJO strongly disturbs fluxes of momentum, heat, and freshwater at the ocean's surface along its pathway from the Indian Ocean to the Pacific Ocean. The direct consequences are changes in the upper ocean structures of currents, temperature, and salinity, and generation of oceanic waves.

Variability in the upper ocean chemistry and biology induced by the MJO is discussed in Section [Atmospheric–Oceanic Chemistry and Biology](#).

Ocean Mixed Layer

The most commonly observed effect of the MJO on the ocean is the intraseasonal perturbation in SST underneath the MJO pathway in the equatorial Indian and Pacific oceans. The average SST anomaly amplitude is typically 0.25 °C, but can be as large as 1 °C in individual cases. The sea surface is warmed during convectively suppressed period of the MJO when there is relatively less cloud coverage and therefore more insolation. The sea surface is cooled by the MJO mainly through enhanced latent heat flux by westerly wind anomalies and reduced insolation by increased cloudiness in and near its convection center ([Figure 4](#)). The cooling can be intensified by upwelling of cold water from below the ocean mixed layer, when the vertical mixing in the upper ocean is particularly vigorous due to extraordinarily strong surface wind. While surface cooling tends to reduce the buoyancy and enhance vertical mixing, this effect is often compensated by an increase in buoyancy by rainfall of the MJO. Abundant freshwater input into the upper ocean during convectively active period of the MJO may create a barrier layer, defined as an isopycnal layer embedded in a deeper isothermal layer. Such a barrier layer makes it difficult for vertical mixing due to surface perturbations to penetrate deep down and thereby isolates the upper ocean from the thermocline. One consequence is quick warming and cooling of the surface layer and a large diurnal cycle of SST during convectively suppressed periods of the MJO when surface wind is relatively weak.

Surface Currents

Another consequence of the strong surface wind of the MJO, especially its westerly wind anomalies, is the acceleration of surface current. The Wyrtki jets are the most striking example. They are narrow (2° N–2° S), eastward currents at the ocean surface (0–100 m) along the equator across the Indian Ocean generated by seasonal mean westerly surface wind during the transition periods (April–May and October–November) between the two monsoon seasons. Due to surface westerly wind associated with the MJO, the Wyrtki jets fluctuate substantially on intraseasonal timescales with amplitude (0.5–2 m s^{−1}) often greater than their seasonal means. Anomalous Wyrtki jets can also occur during other seasons because of strong westerly forcing by the MJO. The intraseasonal variability of the Wyrtki jets exhibits two spectral peaks. Direct MJO forcing results in a 30- to 60-day peak. Resonant excitation of the second-baroclinic-mode waves by the MJO wind at its spectral end of low frequencies and interference between directly forced and reflected ocean waves lead to a 90-day peak.

The MJO also causes intraseasonal fluctuations in the Indonesian Throughflow (ITF), which is the surface current passing through the Indonesian archipelago and acts as the main artery transporting heat and mass from the Pacific Ocean to the Indian Ocean. The intraseasonal spectral peaks of the ITF at 50–60 days are partially due to direct MJO wind forcing and partially due to MJO-forced oceanic waves. In addition, the MJO also induces intraseasonal fluctuations in other ocean

Figure 4 Schematic diagram illustrating the amplitudes of surface forcing of the MJO in terms of the mean plus/minus intraseasonal perturbation in solar radiation flux (Q_{sw}), latent heat flux (Q_{lat}), net heat flux (Q_{net}), precipitation (P), freshwater input ($P - E$), and zonal stress (τ_x), whose direction is marked by horizontal arrows. Downward (upward) pointing arrows and positive (negative) values indicate fluxes into (from) the ocean. The deep (shallow) cloud symbol at the left (right) represents a convectively active (inactive) phase of the MJO, whose zonal scale is indicated at the top. Intraseasonal fluctuations in longwave radiation flux (Q_{lw}) and sensible heat flux (Q_{sen}) are negligibly small and are assumed to be zero. Units are W m^{-2} for the fluxes, mm day^{-1} for precipitation and freshwater input, and N m^{-2} for wind stress. Uncertainties in the net fluxes are 10 W m^{-2} . Zhang, C., 2005. Madden–Julian oscillation. Reviews in Geophysics 43, RG2003. <http://dx.doi.org/10.1029/2004RG000158>.

currents, such as the Somali current and the Indian Ocean south equatorial current.

Waves

The strong surface westerly wind of the MJO often generates downwelling oceanic Kelvin waves that propagate eastward and equatorial Rossby waves that propagate westward along the equatorial waveguide. The downwelling Kelvin waves play an instrumental role in MJO effects on ENSO, IOD, and ITF, among others. When these Kelvin waves reach the eastern boundary of an ocean basin (e.g., Sumatra), they lead to coastal waves that move along the coastlines toward higher latitudes where they cause local impacts, such as large intraseasonal fluctuations in SST near the northwestern coast of Australia.

Sea Level

Sea level fluctuates intraseasonally with amplitudes more than 10 cm in many areas of the Indian and Pacific oceans due to anomalies in MJO-related surface wind and their generated equatorial Kelvin and Rossby waves and coastal waves. Strongest sea level fluctuations in response to the MJO are in the equatorial Pacific, the coastal region of Sumatra, the Bay of Bengal, and the Gulf of Carpentaria. Along the equator, sea level anomalies propagate eastward at the phase speed of the oceanic Kelvin wave. Intraseasonal fluctuations in sea level at higher latitudes are mostly in the coastal region, due to coastal waves originating in the tropics.

Atmospheric–Oceanic Chemistry and Biology

Several types of atmospheric gases undergo intraseasonal fluctuations under the influence of the MJO. Tropospheric ozone shows positive (negative) anomalies in the subtropical regions of the upper-level cyclonic (anticyclonic) circulation east (west) of equatorial MJO convection centers. Tropospheric ozone anomalies associated with the MJO are about 2.5 Dobson units. These

perturbations in tropospheric ozone are related to the vertical displacement of the ozone-rich stratospheric air due to the sinking or rising of the tropopause associated with the cyclonic or anticyclonic circulations generated by MJO convection.

Fluctuations in carbon monoxide (CO) near the tropopause that propagate along with MJO convection have also been observed. Positive (negative) anomalies in CO in the tropopause transition layer (TTL) are colocated with enhanced (suppressed) MJO convection. These CO anomalies are likely generated by vertical transport (or a lack of it) of CO from lower troposphere to the TTL by convective updraft.

MJO-related intraseasonal fluctuations in carbon dioxide (CO_2) are observed in the midtroposphere with an amplitude of about 1 ppmv. The largest positive (negative) CO_2 anomalies are located near enhanced (suppressed) MJO convection. MJO-related vertical motions that transport high (low) CO_2 concentration from the lower (upper) troposphere upward (downward) are likely to be the main mechanism for the midtropospheric CO_2 fluctuations.

The MJO modulates tropospheric aerosol. Positive (negative) aerosol anomalies are found over the equatorial Atlantic Ocean and Africa when MJO convection is suppressed (enhanced) over the equatorial Indian Ocean and suppressed (enhanced) over the equatorial western Pacific. The amplitude of the intraseasonal fluctuations in the aerosol optical thickness is about 0.04. Enhanced or reduced zonal advection by changes in the low-level zonal wind direction associated with the MJO can be a mechanism for the intraseasonal fluctuation in aerosol over the tropical Atlantic Ocean.

There is a regime transition in surface aerosol on intraseasonal timescales over the equatorial Indian Ocean. Prior to an MJO convectively active period, surface aerosol is dominated by submicrometer sulfate aerosol of continental origin. When surface wind becomes strong during and after the MJO convective period with heavy rainfall, the continental aerosol are washed out and sea spray becomes dominant.

The strong surface wind of the MJO can induce entrainment at the base of the ocean mixed layer, which brings nutrient-rich

cold water from below into the mixed layer. In consequence, increases in surface chlorophyll and phytoplankton bloom occur in areas of surface cooling due to the MJO. These have been observed in many tropical and subtropical open oceans and coastal regions, ranging from the Arabian Sea, northern Indian Ocean, Bay of Bengal, Southeast Asia, and Pacific. Anomalies in Pacific surface chlorophyll propagate eastward with the MJO.

Other Impacts

The MJO also impacts many other phenomena of the Earth system. Some of them cannot be labeled as either weather or climate.

Earth's Angular Momentum

The momentum exchange between the atmosphere and the solid Earth is modulated in part by the MJO. A mountain torque is produced when surface Kelvin waves generated by the MJO propagate along the Pacific equator and are intercepted by the Andes and turn into poleward edge waves along the Andes. In consequence, the Earth's angular momentum fluctuates in concert with MJO activity and so does the length of the day (LOD). In periods of strong MJO activity (e.g., boreal winter), the spectrum of LOD shows a 50-day peak. Fluctuations in LOD with the MJO are about 1.5×10^{-3} s.

Tropopause

When MJO convection moves from the Indian Ocean to the western Pacific, the tropical tropopause rises at most longitudes as well as in regions near the MJO convection center. Tropopause (cold-point) temperature drops more than 2 °C. The largest perturbations occur in the subtropical cyclonic vortices on the polar sides of the MJO convection center. In the tropical (10° S–10° N) TTL, mean cirrus fraction doubles, with its maximum over equatorial Africa and South America.

Near the tropopause, water vapor and cloud ice water content fluctuate intraseasonally with the MJO deep convection. Within the range of 120 ppmv, intraseasonal fluctuations in upper-troposphere (215 hPa) moisture propagate eastward with MJO convection center over the Indian and Pacific oceans. Anomalies in moisture coherent with the MJO are out of phase at the 215 and 100 hPa levels. Anomalies in ice water content are about $\pm 2 \text{ mg m}^{-3}$ at 215 hPa and decrease upward. Positive ice water content anomalies are located in the region of enhanced MJO convection.

ITCZ

The MJO influences the breakdown of the Pacific ITCZ. Deep convective clouds in the ITCZ yield to shallow convection when MJO zonal wind switches from the westerlies to the easterlies and the atmospheric environment for deep convection changes from neutral to suppressing. The eastward propagation signal of the MJO over the eastern Pacific is the most robust in the ITCZ. Coincident with the eastward propagation of MJO, there is a tendency for ITCZ convection to move northward. Convective initiation of the MJO over the Indian Ocean interrupts the ITCZ south of the equator. Interaction between the MJO and Atlantic

ITCZ is a potential mechanism for hurricane genesis. Precipitation in the Atlantic ITCZ is enhanced when the MJO convection center is over either the Indian Ocean or the western Pacific Ocean, but reduced when it is over the Maritime Continent.

Diurnal Cycle

Diurnal cycles in both the atmosphere and upper ocean from the tropical Indian Ocean to the western Pacific are modulated by the MJO. The diurnal cycle in convection over continental land and islands is much stronger during periods of suppressed convection of the MJO due to strong diurnal heating at the surface. In periods of active convection of the MJO, daytime insolation is reduced by enhanced cloudiness and mesoscale convective systems become prominent, which may last beyond one day. These tend to overwhelm diurnal forcing of convection and substantially reduce diurnal signal in convection. Over the ocean, a strong diurnal cycle in SST occurs during convectively suppressed periods of the MJO when surface wind is weak, daytime solar heating is strong, and nighttime radiative cooling is effective in inducing buoyancy driven vertical mixing. During convectively active periods of the MJO, strong surface wind generates constant mixing, which smears diurnal heating and cooling, hence a weak diurnal cycle in SST.

Concluding Remarks

The broad impacts of the MJO on global weather, climate, and many other phenomena are a strong testament of the unique role of the MJO in connecting weather and climate and affecting many aspects of the Earth system. Hardly can any other single atmospheric phenomenon be found which is even close to the MJO in this regard. Because of this unique role, improvement of MJO prediction can potentially lead to advancement in prediction of many other phenomena in the Earth system. It has been demonstrated that numerical models that produce more realistic MJO signals are capable of predicting many other phenomena, such as TCs and extratropical circulation patterns, with a longer lead time. It is clear that advancement of Earth system prediction must be achieved with a better understanding and prediction of the MJO.

Greenhouse Effect

GR North, Texas A&M University, College Station, TX, USA

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

The Earth's climate is determined by a balance between the rate of radiation energy from Earth to space and by the rate of its receipt and absorption from the Sun. The radiation rate to space increases rapidly with temperature, so that if the rate of heating exceeds that of cooling to space, the planetary temperature will rise leading to increased radiation emitted until the balance is restored. If there is a deficit, the reverse will happen. When greenhouse gases such as CO₂, CH₄, and H₂O are in the air, they cause the effective altitude of emission to space to be higher in the atmosphere where it is colder. This effect reduces the radiation to space for a given surface temperature. This reduction of emitted radiation means the planetary temperature will increase until balance is reestablished. This article addresses the question of the response of the surface temperature field to a doubling of CO₂, for the case where no feedback mechanisms are operating. The value found is $1.0 \pm 0.1^\circ\text{C}$, a value often quoted in the literature. Various feedback mechanisms can multiply or diminish the response. These include positive feedback mechanisms such as water vapor, ice-albedo; negative feedback mechanisms include lapse rate. Cloud feedback is not yet fully understood, but the balance of evidence suggests that it is positive.

Introduction

The greenhouse effect refers to the complex of phenomena starting with the passage of visible light from the Sun through the atmosphere essentially unattenuated to be absorbed by and warming the surface. The cooling to space by emitted radiation is inhibited by gases present in the atmosphere that absorb radiation and essentially trap the heat from escaping to space as efficiently as would otherwise occur. The effect was first considered by Joseph Fourier, the famous French mathematician and philosopher in the 1820s. Later in that century John Tyndall isolated a number of gases such as H₂O and CO₂ and showed that they are absorbers of infrared radiation (he called it *heat radiation*), but that the dominant (>99.9% by molecule count) constituents of Earth's atmosphere (N₂, O₂, and Ar) are transparent in both the visible and the infrared. Later scientists such as Arrhenius, Calendar, and Plass took an interest in the problem, eventually leading up to the modern study with sophisticated general circulation models of the atmosphere (the most remarkable of which is [Manabe and Wetherald, 1975](#)). The history of this exciting course of research is presented by [Weart \(2009\)](#). The atmospheric greenhouse effect is much more subtle than the analogy with a building with a glass roof that does cause a warmer interior, but increasing the glass thickness has no effect because the glass already absorbs all of the upwelling radiation. Instead in the real atmosphere the upward passage of infrared radiation through the atmosphere is strongly affected by the vertical dependence of temperature of the air and the changes in absorptivity of the greenhouse gases with air pressure. Moreover, the absorption of infrared radiation by greenhouse gases in the atmosphere depends very strongly on the distribution of energy over wavelengths of the emitted infrared radiation. The calculation is complicated and requires accurate and detailed knowledge of infrared absorption spectra for each gas. At this time, we are confident that we have adequate computer algorithms and empirical information to make these calculations for clear skies to an accuracy adequate for predicting the effects of changes in the concentration of the common greenhouse gases. A useful collection of

scientific papers from the recent period is collected in the volume edited by [Archer and Pierrehumbert \(2011\)](#).

The Earth's average surface temperature is about 289 K. For a blackbody at this temperature the emission spectrum peaks at around 10 μm (1 μm denoted $\mu\text{m} = 10^{-6}\text{ m}$), which lies in the infrared portion of the spectrum. The dominant gases in the Earth's atmosphere are N₂ (78.084% by molecule count), O₂ (20.946% by molecule count), and Ar (0.934% by molecule count). None of these species absorb in the infrared portion of the electromagnetic spectrum. On the other hand, there are some trace gases that are well mixed throughout the atmosphere (up to hundreds of kilometers) such as CO₂, CH₄, and N₂O that do absorb and emit radiation in parts of the infrared band of wavelengths. For convenience, let us call these gases GHGs. Ozone (O₃) is a strong greenhouse gas and is variable in the troposphere (since its lifetime in the troposphere is of the order of weeks, too short for homogenization over the globe). It is abundant in the stratosphere where it is produced by photolysis (dissociation of molecular oxygen or other species by ultraviolet or X-rays from the Sun to give free O atoms, leading to their subsequent combination with O₂, releasing heat). In addition, water vapor is a strong absorber and emitter in the infrared, but its concentration or mixing ratio (ratio of its number of molecules per unit volume to that of background air, often given as parts per thousand or parts per million) is not uniformly mixed in the atmosphere. Its mixing ratio is strongly diminished in the vertical because of condensation as the temperature falls below the saturation value for the vapor. Water vapor's short turnover time in the atmosphere and the heterogeneous source locations at the surface lead to spatial nonuniformities that can last for days. The condensation process causes the vertical scale height to be only a few kilometers, compared to 8–15 km (depending on latitude and season) for the dry air and the well-mixed GHGs listed above. Water vapor even in trace amounts in the upper troposphere and stratosphere is a strong absorber and emitter of infrared radiation. So technically water vapor is a GHG as well but it is mainly controlled by the temperature and the availability of liquid water at the local surface.

Earth's Climate without Greenhouse Gases

Suppose there were no GHGs in the atmosphere. If that were the case, we could compute the globally averaged surface temperature from balancing the rate of outgoing infrared radiation to the rate at which solar radiation is absorbed. The amount of radiation to space in this case would be $4\pi R^2 \sigma T^4$ where $\sigma = 5.67 \times 10^{-8} \text{ J m}^{-2} \text{ s}^{-1} \text{ K}^{-4}$, the Stefan-Boltzmann constant, and R is the Earth's radius. The rate of energy absorbed is $\pi R^2 S_0(1 - \alpha_p)$ where S_0 is Total Solar Irradiance (TSI, the amount of radiation energy per second from the Sun impinging on a one square meter surface perpendicular to the solar beam at the annual average distance of Earth to the Sun), which has the value 1360 W m^{-2} (the TSI is also known as the solar constant), and α_p is the planetary albedo (or reflectivity to sunlight). The current value of α_p is about 0.30, but this includes clouds and snow/ice. For a planet with no GHGs there would be no snow/ice or clouds (as we know them, anyway). Hence, we will take a conservative estimate of 0.10 for the albedo. Equating the rates, we obtain a value of $T = 271 \text{ K}$. Using $\alpha_p = 0.2$ yields 263 K . Both are unacceptably cold when compared to the observed present temperature of 289 K . The presence of the GHGs is the reason.

A Gray Greenhouse

To gain some understanding of how the greenhouse effect works consider the planet above, but surround the planet with a thin spherical shell, which is transparent to solar radiation but partially absorbing to terrestrial (infrared) radiation. The surface now receives radiation not just from the Sun but also from downwelling infrared radiation from the shield, which is itself a material surface capable of emitting radiation both upward and downward. The total rate absorbed at the surface is $\pi R^2 S_0(1 - \alpha_p) + 4\pi R^2 \epsilon \sigma T_{\text{sh}}^4$, where $\epsilon(0 \leq \epsilon \leq 1)$ is the shield's emissivity (also its absorptivity, a rule known as Kirchoff's Law) and T_{sh} is the temperature of the shield. The ground radiates upward at a rate $4\pi R^2 T_{\text{surf}}^4$. The shield is now a player as well and needs its own energy balance equation. It radiates both upward and downward at a rate $4\pi \epsilon R^2 T_{\text{sh}}^4$. It absorbs infrared radiation upwelling from the surface at a rate $4\pi \epsilon R^2 T_{\text{surf}}^4$. We have the balance equations for the shield (after canceling common factors):

$$S_0(1 - \alpha_p) = 4\sigma T_{\text{surf}}^4 - 4\epsilon \sigma T_{\text{sh}}^4, \quad \text{surface balance} \quad [1]$$

$$T_{\text{surf}}^4 = 2T_{\text{sh}}^4, \quad \text{shield balance} \quad [2]$$

leading to:

$$T_{\text{surf}} = T_{\text{surf}}^0 \left(\frac{1}{1 - \frac{\epsilon}{2}} \right)^{\frac{1}{4}} \quad [3]$$

where T_{surf}^0 is the surface value at $\epsilon = 0$, the case of a transparent and therefore nonparticipating shield. Note that the surface temperature is largest at $\epsilon \rightarrow 1$. Inserting an 'optically thick' or 'black' infrared shield increases the Kelvin temperature at the surface by a factor of $2^{\frac{1}{4}} = 1.189$, the largest warming a single shield can cause. This is at best a very crude estimate of the greenhouse effect in the real atmosphere. We could add

more gray shields, each in 'radiative equilibrium' in terms of their own temperatures, and thereby make this greenhouse effect stronger. Note how different this multiple shield case is from simply thickening the glass in a greenhouse, which is equivalent to increasing ϵ . One flaw of the gray-atmosphere approach is the fact that the absorption of the GHGs at different wavelengths is hardly constant. In fact, it is highly irregular. In the next section, we look at some illustrations with more realistic details of the infrared spectra emitted by the individual greenhouse gases in an idealized column of air.

Infrared Spectra of Outgoing Radiation

In this section, we go a step further and examine the detailed spectrum of the outgoing radiation. Many decades of laboratory and theoretical research on molecular absorption spectra have led us to a very detailed understanding of the relevant parameters such as line intensities and the pressure and temperature dependences of line widths. The term 'line' is used here to indicate that infrared absorption spectra are mostly composed of series (typically millions) of very narrow but strong spikes as a function of wavelength. The spikes are the result of 'resonant' absorption at the natural frequencies of the molecules as they rotate and vibrate, these frequencies can be understood through the treatment of molecular dynamics via quantum mechanics. Integrals over intervals in wavelength must treat the distribution of these spikes and other discontinuities carefully.

Through the same historical period radiation transfer computer algorithms have been improved to the point that under ideal conditions such as no clouds or aerosols, we can compute the spectrum of outgoing radiation to space with high accuracy. Satellite observations with high-resolution infrared spectrometers have also verified the calculations. Here for demonstration purposes, we use an early version of the program that is available to the public called MODTRAN. A simplified version of it is available in the form of a calculator at the Web site (<http://forecast.uchicago.edu/modtran.html>, developed by David and Jeremy Archer; we refer to this as the Chicago Web site). The program takes a specific latitude belt (in our case the tropics) and specifies sky conditions (in our case *clear* with no precipitation or clouds). The user can specify the (vertically uniform) tropospheric mixing ratios of methane and carbon dioxide and ozone's climatological profile can be scaled up or down by a constant factor. The surface temperature can be given but once entered into the calculator the vertical dependence of temperature (the lapse rate) is constrained to the climatological profile at the latitude belt chosen (here tropical). Constraining the lapse rate implies that some vertical transport of heat is occurring in the atmosphere along with the radiation transfer of energy. The program then assigns a vertical distribution of the greenhouse gases, temperature, and air density appropriate to the latitude and mixing ratios of the GHGs as specified by the user. The vertical distribution of water vapor is adjusted to be in equilibrium with the climatological temperature profile as given in the calculator model (either fixed relative humidity or fixed vapor pressure). We chose the clear-sky tropics for our example because the tropopause is very high allowing very cold temperatures at its highest points

Figure 1 Vertical profile of the temperature in the clear-sky tropics used in this exercise and specified in the MODTRAN calculator model based on the Web site: <http://geoflop.uchicago.edu/forecast/docs/Projects/modtran.orig.html>.

(≈ 195 K) with an average lapse rate of nearly 10 K km^{-1} . **Figure 1** shows the vertical dependence used by the calculator model for the clear-sky tropics. These conditions give a maximum greenhouse effect. A number of other minor greenhouse gases are included in the standard program (such as N_2O , NH_4 , and the chlorofluorocarbons) and are fixed at climatological profiles.

Figure 2 shows the spectrum of outgoing radiation ($\text{W m}^{-2} \text{ cm}^{-1}$) as a function of wave number (cm^{-1}). (Wave number is defined as the inverse of wavelength. It is proportional to the frequency of the electromagnetic radiation, c/λ , where c is the speed of light. Wave number is used in infrared spectroscopy because it is easily related to the molecular structure of the molecules involved.) This first case includes all

greenhouse gases at or near their present concentrations. The infrared flux is for the clear sky in the tropics. Incidentally, all computations are conducted in this version of MODTRAN with spectral resolution of 2 cm^{-1} . (The most accurate calculations are the so-called Line-by-Line (LBL) codes. These take into account each individual line and its width, the latter varying with altitude. Such calculations are very important for benchmarking approximate radiative transfer codes such as MODTRAN and testing against measurements, but LBL codes are too consumptive of computer time to be used directly in climate model calculations.) If there were no carbon dioxide in the atmosphere the spectrum would be the blue curve denoting blackbody radiation at 300 K. Also shown in green is the blackbody curve for an emission temperature of 215 K. The

Figure 2 Outgoing infrared spectrum for the Earth's tropical clear-sky atmosphere with all greenhouse gases present. The abscissa is wave number in cm^{-1} , while the ordinate is $\text{W m}^{-2} \text{ cm}^{-1}$. The blue curve is the emission spectrum expected for a 300 K blackbody radiator and the green line is for a 215 K emitter. The area under the curves is proportional to the energy flux density between the horizontal limits on the abscissa. Adapted from calculations based on the Web site: <http://geoflop.uchicago.edu/forecast/docs/Projects/modtran.orig.html>.

large negative departure (the 'ditch') between wave numbers 600 and 800 cm^{-1} is due to the presence of CO_2 . Notice that the emission around 680 cm^{-1} is at an emission temperature of 220 K, a temperature about 25 K above that of the tropopause in the tropics (see Figure 1). The spike in the center (located at 667.4 cm^{-1}) of the band is due to a very strong narrow feature in the CO_2 absorption/emission spectrum. This feature is so strong and hence the result is a spike emerging from the floor of the ditch.

There are a number of interesting features besides the main ditch in Figure 2. For example, there is another, but smaller, ditch at about 1100 cm^{-1} due to the GHG ozone (O_3). Note that the emission surrounding the ozone ditch from around 800 to about 1250 cm^{-1} hugs the blue 300 K emission spectrum for a blackbody whose surface is at 300 K, the surface temperature specified in this simulation. This broad band is called the 'atmospheric window,' a range of wave numbers where water vapor has almost no absorptivity so that the radiation in this band is coming almost directly from the Earth's surface (this turns out to be important when clouds are present). Left of the main CO_2 ditch is a wide band of emission that is coming from cooler emission temperatures. This is mainly coming from layers of water vapor well above the surface. The same holds for wave numbers beyond 1250 cm^{-1} , except that methane is also playing a role there. The main point of Figure 2 is that greenhouse gases reduce the outgoing radiation from that of a blackbody at 300 K by about 60 W m^{-2} .

As a second example consider the planet with only one GHG, CO_2 , at a nominal concentration of 375 ppm. Figure 3 shows this case wherein the same conditions as Figure 2 apply (temperature at the surface, 300K, tropical clear sky), except that there are no other GHGs. We see the CO_2 ditch clearly but no other prominent features. Consider the bottom of the ditch. The bottom follows the 220 K blackbody curve (see the green 215 K curve in Figure 2), except for the spike in the center of the ditch. Why 220 K? This is because the tropopause temperature is at this level in this particular simulation. As shown in Figure 1, the temperature in the troposphere falls off nearly linearly from the surface (300 K) to the tropopause (195 K)

then begins to increase steeply in the lower stratosphere. As we increase the concentration of CO_2 in the air column, the level at which the emission to space occurs rises. As this level rises, the emission temperature lowers until the tropopause is reached. This explains the tilted, flat bottom of the ditch. The spike is due to a very strong CO_2 emission line (actually a convergence of many lines) at the center of the ditch. The emission level of this line is well above the level corresponding to neighboring wavelengths in the ditch and it hits the tropopause when the CO_2 concentration reaches a mere 25 ppm. As the concentration of CO_2 in the air column increases the spike's emission level (being in the stratosphere) actually goes down. In other words, the spike tends to cool the atmospheric column as the concentration is increased. The decrease in outgoing radiation is not at the tilted flat bottom of the ditch but rather in the 'wings' of the ditch.

What determines the emission altitude of the CO_2 ? It varies by wave number as should be expected. Since a good emitter is also a good absorber, we can visualize the emission altitude by considering a downwelling beam at a particular wave number interval. The downwelling beam is attenuated by the CO_2 absorber proportional to its local density and its absorptivity. As one descends into the atmosphere more of the beam is attenuated by CO_2 and when the absorption reaches a value e^{-1} , where e is the base of the natural logarithm ≈ 2.718 . As viewed from above this level is the location of 'unit optical depth.' This level is also roughly the average level of emission (it is called the 'Chapman Level'), but it is smeared out over about one unit optical depth. Now we can see that as the total concentration of CO_2 is increased and because it is constrained to be exponentially distributed in the vertical (well-mixed), the Chapman Level must increase.

Figure 4 shows the result of doubling the concentration of CO_2 from 375 to 750 ppm in the case where no other GHGs are present. The range of wave numbers focusses on the band of wavelengths covering the ditch in order to see more clearly the changes in the outgoing spectrum. As the CO_2 concentration is doubled, the flat portion of the ditch is unaffected, but the wings of the ditch are clearly deepened by a small amount. The

Figure 3 The outgoing infrared radiation spectrum for the Earth's tropical clear-sky atmosphere where the only greenhouse gas present is CO_2 at a mixing ratio of 375 ppm.

Figure 4 The outgoing infrared spectrum in the range $550\text{--}770\text{ cm}^{-1}$ at mixing ratios of CO_2 at 375 ppm (black) and 750 ppm (red). The blue dotted curve is the emission spectrum expected for a 300 K blackbody radiator and the green dotted line is for a 215 K emitter. Adapted from calculations based on the Web site: <http://geoflop.uchicago.edu/forecast/docs/Projects/modtran.orig.html>.

changes in the wings seem tiny, but the integral over the ditch (and small contributions elsewhere) reveal (the Chicago Web site simulator tells us) that the infrared radiation is reduced by 4.4 W m^{-2} .

We show one more experiment where low concentrations of CO_2 are doubled twice as shown in Figure 5. Again the range of wave numbers in the figure spans the CO_2 ditch. In this case, the emission from the ditch decreases with CO_2 increases and the greenhouse effect spreads all across the ditch including both the floor and the wings. This is to be contrasted with the higher initial concentrations experiment of Figure 4. We can now explain the reversal of change in the floor of the ditch compared to the wings. In the lower concentration cases, the brightness temperature is well below the tropopause (except for the tiny spike in the very center of the ditch where the very

strong absorption feature lies). As the concentration is increased, the strong absorption spike at the center shallows (the spike grows), but the floor of the ditch deepens because the radiation to space is originating from higher and cooler layers of the troposphere. When the concentration becomes large enough the brightness temperature actually reaches a minimum and even turns around as the level of last radiation enters the inverted temperature profile of the lower stratosphere. It is interesting that the brightness temperature never falls to 195 K, which is the minimum in the temperature, as seen in Figure 1. This is because the distribution of radiation origins in the continuous vertical profile is from a 'smear' or integrated aggregate of infinitesimal levels of the order of one optical depth and its effective value is not at the actual minimum of the distribution.

Figure 5 The outgoing infrared spectrum in the range $550\text{--}770\text{ cm}^{-1}$ at mixing ratios of CO_2 at 40 ppm (black), 80 ppm (red), and 160 ppm (purple). The blue dotted curve is the emission spectrum expected for a 300 K blackbody radiator and the green dotted line is for a 215 K emitter. Adapted from calculations based on the Web site: <http://geoflop.uchicago.edu/forecast/docs/Projects/modtran.orig.html>.

So far in these exercises, we have kept the surface temperature fixed. That is, we have not forced the incoming absorbed rate to balance the outgoing. Adjusting the surface temperature to come into exact balance would not be proper because the incoming and outgoing rates do not balance in a finite width latitude belt because transport of heat to (and from) neighboring latitude belts contributes to the energy balance. Although we seek to know the outcome if CO₂ is doubled, we will not be able to do this exactly because it is the entire globe that is to be balanced, not just the tropics. Nevertheless, we can do an approximate job of it by adjusting the temperature upward in the column of air until the outgoing radiation is the same as before. When we adjust the ground temperature, we will hold the water vapor fixed at zero mixing ratio. (Actually, the MODTRAN code used here has some water vapor above about 12 km but it is held fixed during any changes.) We can iteratively change the ground temperature incrementally until the outgoing radiation is restored to the value it had when CO₂ was at 375 ppm. After this adjustment we find that the required temperature increase is about 1.10 K, a value within a few percent for the global average change found in LBL calculations (Myhre et al., 1998).

We can do a few more cases to improve our insight into the changing greenhouse effect due to doubling of CO₂. First consider the MODTRAN simulation when clouds are present (but still no other GHGs, slightly absurd since clouds are made of water droplets). The result is that for cloudy atmospheres in the tropics, we simply replace the broad band ground emission in Figure 3 with the temperature at cloud top – the ditch remains unaltered. In other words, the cloud tops in most cases are much lower than the emission level of the CO₂. The change in surface temperature to restore the outgoing radiation to its lower CO₂ concentration is left unchanged from the cloud-free case if we assume that the changes in temperature aloft are carried all the way through the clouds to the ground. We can use MODTRAN in another series of experiments with summer and winter middle latitude conditions. Perusing these cases (with no GHGs other than CO₂) reveals very little difference from the tropical case. We conclude that given the approximations inherent in MODTRAN the change in temperatures will be of the order of between 0.9 and 1.1 K for a doubling of CO₂ from 375 to 750 ppm, and since the dependence on CO₂ mixing ratio is logarithmic, we can expect the doubling effect to be about the same for doubling from any base level. (Some authors prefer to start with preindustrial levels of 250 ppm.)

Summary of Assumptions

We have executed some thought experiments leading us to believe that the increase in global average temperature due to a doubling of CO₂ is about 1.0(±0.1) °C. We have cautioned that the physical model and the approximations to it are pretty schematic but have pedagogical value. We have to be careful not to apply the quantitative result to the real world without reviewing the assumptions that went into our calculation.

1. We used clear sky only in the calculations. While the presence of fixed (in their fractional coverage and altitudes) clouds (cloud tops are below the emission levels of CO₂ and

water vapor) would not have an appreciable effect on the response to doubling CO₂, the assumption of ‘fixed’ is not likely to hold. Cloud feedback processes are among the most challenging problems facing the climate science community. Much of the difficulty stems from the fact that many cloud processes are at smaller or comparable scales to the grid spacing of our climate models. But clouds are also hooked to the larger scales of the general circulation of the atmosphere, for example, the midlatitude storm belts, which might be undergoing secular change with global warming.

As mentioned earlier, the horizontal distribution of water vapor is nonuniform and temporally variable. The precise effect of this phenomenon is still a matter of ongoing research. For example, how well do we need to incorporate such space–time nonhomogeneities in our climate models.

2. Following the Chicago Web site, we adjusted the temperature ‘rigidly’ up the whole column when we changed the surface temperature. This is probably not what actually happens in the air column. The lapse-rate profile might change as the surface temperature is raised and this is likely to lower the response. This effect is called the lapse-rate feedback and it is probably negative.
3. In increasing the temperature to compensate for the reduced outgoing radiation we ignored that fact that the atmospheric column will now hold more water vapor because of the strong dependence of saturation vapor pressure on air temperature. That roughly constant relative humidity is supported by climatology and model simulations. This positive feedback is likely to be strong, possibly increasing the response by a factor of two. Lapse-rate and water vapor feedbacks are anticorrelated, but water vapor appears to be much stronger based on climate model simulation studies.
4. Other known feedbacks such as those due to snow and ice cover are also ignored. These are positive feedbacks but are thought to be smaller than the combination of water vapor, lapse-rate, and cloud feedbacks.
5. As the CO₂ increases, changes in the temperature of the stratosphere will occur along with those of the troposphere. Generally to maintain balance of air layers in the stratosphere, the temperature there will have to decrease during greenhouse warming below. This comes about because convection mixes the air in the troposphere, but the stratospheric layers are not coupled to the troposphere through convection. Basically, the stratosphere does not know the troposphere is warming as regards convective overturning, so the cooling in the stratosphere due to increased CO₂ leads to a lowering of stratospheric temperatures.
6. We ignored the rest of the planet. Middle and higher latitudes may have quite different sensitivities to GHG concentrations. If the tropics exhibit the largest sensitivity, this will have to be mixed with that of less sensitive latitude belts.
7. There are likely to be slow feedbacks in the system that alter the composition of the atmosphere including its GHGs. These feedbacks may take decades or even centuries to kick in, as permafrost is melted or GHGs are released from sources deep in the oceans and terrestrial biosphere.

8. A final consideration. [Figure 4](#) shows the differential of radiation as a function of wave number across the ditch. Much here depends on the height of the tropopause on the year, month, or even the day of the occurrence. This is one source of variability of the sensitivity of climate. We could also ask whether a steadily increasing altitude of the tropopause due to global warming represents an additional feedback in the system.

Climate feedback mechanisms are considered in more detail in article [Climate and Climate Change: Climate Feedbacks](#) in this Encyclopedia.

While the exercises presented above are instructive, we cannot end the story at this point. The only way to accurately simulate the response to CO₂ is through a general circulation model of the atmosphere. This is a formidable task given that many of the important processes are not yet well represented in the models.

Conclusion

The Earth's surface temperature has been rising steadily over the last century. Most of the potential drivers of climate change (volcanic activity, solar brightness variability, atmospheric aerosols, and greenhouse gas concentration increases) have been examined in great detail in recent years. We now have reasonably good estimates of the strengths and time dependences of these drivers and although much needs to be done in substantiating these assertions, virtually all have been eliminated except for the increasing influence of GHGs. The importance of this driver is also consistent with paleoclimate evidence. We have shown a series of pedagogical computer experiments that provide estimates of the response in the tropics to doubling the CO₂ concentration while excluding all feedbacks. These experiments can be repeated by the reader by going to the Chicago Web site. While virtually all experts on the radiative aspects of climate science would agree with the values we have obtained, we have to acknowledge that many additional physical effects will come into play along with intensification of any of the primary drivers. Some of these additional physical effects (feedbacks) are likely (at this writing) to amplify the response to CO₂ doubling to a value perhaps as much as four times.

One more important effect not considered here is the time dependence of the response. The illustrations used here were from one equilibrium climate state to another equilibrium state. The Earth system has a number of effective heat storage components that have varying effective heat capacities. Among these are the atmospheric column with a response time of about a month, the oceanic mixed layer with a response time of a few years, continental glaciers with centuries of response time, and finally the deep ocean which communicates with the surface waters through small passageways that limit the flow of heat toward the deeper parts of the world ocean. Many parts of the deep ocean have not touched the surface in 800 years. The upshot of this is that while climate sensitivity is an important index for comparing one atmospheric model with another, the global system has many interlocking parts that cause the response of the surface to be delayed in its full response by perhaps hundreds of years. This means that even if we were to stop or reverse the rate of greenhouse gases entering the atmosphere, the reversal of the response is likely to be delayed by these sluggish and nearly inaccessible components.

Synopsis

People understood since antiquity that climate could change locally, but nobody imagined that human activity could alter global climate. In 1896 Arrhenius and in the 1930s Callendar promoted a theory of anthropogenic global warming caused by a buildup of carbon dioxide. Few found this plausible until the mid twentieth century, when new theoretical work and observations showed that the concept had to be taken seriously. In the 1970s, complex computer models suggested a risk of several degrees of warming in the following century. The temperature–carbon dioxide connection was supported by the paleontological evidence from deep ice cores. Uncertainties about the effects of aerosol pollutants and clouds complicated the issue. Nevertheless, around the start of the twenty-first century, improved computer and paleontological arguments, plus a prolonged observed warming of the planet, led to consensus statements by international panels that warned of severe impacts.

The nineteenth century discovery of ice ages in the distant past proved that climate could change radically and on a global scale. Could human civilization have any influence on such processes? From ancient times, people had suspected that their activities could change the climate locally. Scholarly theories and folk beliefs speculated that chopping down a forest, irrigating a desert, or draining marshlands might change the temperature and rainfall in the vicinity. Americans in the nineteenth century argued that settlement of the country had brought a less savage climate, and farmers who moved onto the Great Plains boasted that ‘rain follows the plough.’ Some European scientists, however, argued that deforestation made for a drier, not wetter, climate. By the end of the nineteenth century, meteorologists had accumulated enough reliable weather records to test whether rain follows the plough or flees from the axe. Both ideas failed the test. Even the transformation of the entire ecosystem of eastern North America from forest to farmland had apparently made little difference to climate. If the spectacular changes wrought by humankind could not alter a region’s climate, there seemed still less reason to imagine that they could alter the planet as a whole.

Through the first half of the twentieth century, scientists who studied climate treated not only humanity but the entire biological system as passive. Deserts and forests expanded or shrank in helpless response to climate changes. The cause of these changes might be, for example, the diversion of winds when mountain ranges arose or eroded away, or an alteration of ocean currents when some isthmus opened or closed, or variations of the Sun’s heat, or a spate of volcanic eruptions pouring smoke into the air. Whatever the cause, it was surely a force far mightier than anything done by the meter or so of organic matter that covered some patches of the planet’s surface. Still less could the tiny activities of humanity be compared with the grand forces of geophysics. The scale of time was also grand, for scientists thought that ice ages and other significant changes unfolded over many tens of thousands of years. Within the time span of a few human generations, climate was thought to be held stable by a benign ‘balance of nature.’

One theory for the cause of climate changes looked at the composition of the atmosphere.

In memoirs published in 1824 and 1827, Joseph Fourier calculated the temperature of a body at Earth’s distance from the Sun: he got a temperature well below freezing, much colder than the actual planet. The difference, Fourier recognized, was due to the atmosphere. Somehow it kept part of the heat radiation in. He tried to explain this by comparing Earth with its covering of air to a box with a glass cover. Visible light warms the surface, but the atmosphere (like the glass) prevents the invisible heat energy from escaping. This was the effect that would later be called, by an inaccurate analogy, the ‘greenhouse effect.’

John Tyndall, curious about the cause of ice ages, set out to find whether there was in fact any gas in the atmosphere that could trap heat rays (infrared radiation). In 1859, his careful laboratory work identified several gases that did just that. The most important was simple water vapor. Also, effective were carbon dioxide (CO₂) and methane (CH₄). Tyndall likened these gases in the atmosphere to a dam built across a river. Just as the dam made the water deeper, he explained, so the atmosphere, by blocking outgoing radiation, raises the temperature at Earth’s surface.

Some speculated that ice ages began and ended when volcanoes became less or more active in emitting such ‘greenhouse gases.’ In 1896, Svante Arrhenius published laborious calculations, which he believed showed that a severe drop in atmospheric CO₂ would in fact bring a lowering of temperature sufficient to cause an ice age. He went on to a new idea: as humanity burned fossil fuels such as coal, enough CO₂ was added to Earth’s atmosphere to influence the climate. If the concentration of the gas in the atmosphere doubled (which Arrhenius figured would take thousands of years), the planet’s average temperature would be raised by a few degrees. In retrospect it was shown that Arrhenius’ calculations were inadequate; he had not proved that greenhouse gases would significantly change climate, but he had at least shown that this was a possibility.

Arrhenius’ idea was only one of many speculations about climate and not the most convincing. Scientists found good reason to believe that the emissions could not change global climate significantly. For one thing, experiments and theoretical considerations seemed to show that the absorption of

infrared by CO₂ in the atmosphere was saturated: adding more gas would make no difference since the radiation was already fully blocked. For another, the oceans would absorb CO₂ as fast as industry emitted it.

In the 1930s, old people began to notice that the United States and the North Atlantic region had warmed significantly since their childhoods. Meteorological records confirmed it. Scientists supposed this was just a phase of some mild natural cycle, with unknown causes. Only one lone voice, that of the engineer Guy Stewart Callendar, insisted that greenhouse warming was on the way. He had evaluated the old measurements of atmospheric CO₂ concentrations and concluded that over the past hundred years the concentration of the gas had increased by about 10%. This rise, Callendar asserted in 1938, could explain the observed warming. He argued that even if the CO₂ presently in the atmosphere thoroughly blocked outgoing infrared radiation, adding more gas must make for more surface warming, by raising to a higher and colder level the point in the atmosphere from which radiation ultimately escaped. His arguments failed to convince meteorologists.

In the 1950s, Callendar's claims provoked few scientists to look into the greenhouse effect with improved techniques and theories. Roger Revelle and colleagues studied the absorption of CO₂ by the oceans. In 1957, he demonstrated that, with human population and industry both climbing exponentially, the oceans could not in fact absorb the gas fast enough to keep it from building up in the atmosphere. Charles David Keeling drove home the point in 1961 with meticulous measurements showing that the concentration of the gas in the air was in fact rising, year by year, as Callendar had claimed.

Meanwhile, Gilbert Plass took up the challenge of calculating the transmission of radiation through the atmosphere and nailed down the fact that adding more CO₂ would markedly increase the interference with infrared radiation. He calculated that doubling the concentration – which he thought would take a few centuries to happen – would bring a 3–4 °C average rise. But Plass's calculation, like Arrhenius's and others up to that time, did not take into account the possible changes in cloudiness and many other features of the real atmosphere. It could not be accepted as a reliable calculation of the greenhouse effect.

Over the next decade, a few scientists devised simple mathematical models of the climate. The models included feedbacks that made the system surprisingly variable. For example, if a little extra warmth melted northern snow and ice earlier in the spring, the dark soil and water would absorb sunlight and warm up the Arctic still more. Other scientists figured out ingenious ways to retrieve past temperatures by studying ancient pollen in bogs and fossil shells in the clay of sea floors. The data showed that grave climate changes had happened within as little as a few centuries.

This finding was reinforced by computer models of the general circulation of the atmosphere, the fruit of a long effort to learn how to predict the weather. Applying basic physics equations to calculate the climate, by the mid 1960s these models were able to roughly reproduce trade winds, desert regions, Arctic ice, and other features of the planet. A 1967 computation by Syukuro Manabe and colleagues incorporated clouds, convection of heat to upper levels of the atmosphere, and other crucial features neglected in the simple

earlier models. Their results suggested that doubling the concentration of CO₂ – which was now seen to be likely by the end of the twenty-first century – would raise the planet's average temperature by a few degrees. It was understood, however, that much more work would be needed before such results could be relied upon.

In the early 1970s, a series of unusual droughts and food shortages helped turn curiosity about the climate into anxious concern. Alongside greenhouse gases, Reid Bryson and some other scientists pointed out that human activity was putting ever more dust and smog aerosols into the atmosphere. Perhaps this haze would block sunlight and cool the world. Meanwhile, painstaking compilation and analysis of Northern Hemisphere weather statistics showed that a cooling trend had begun in the 1940s. Scientists were uncertain, sometimes predicting a balmy globe with coastal areas flooded as the ice caps melted and sometimes seeing a risk of a catastrophic new ice age. Study panels, first in the United States and then in Europe, warned that some kind of future climate change might pose a severe threat. The only thing most scientists agreed on was that they did not yet understand the climate system well enough to predict what kind of dangerous changes might be in store.

Research activity accelerated, including huge data-gathering schemes that mobilized international fleets of oceanographic ships and orbiting satellites. As computer models improved, by the late 1970s they showed clearly that warming, not cooling, was likely in the future. Inspecting models devised by Manabe's team and a team under James Hansen, a panel of the National Academy of Sciences concluded in 1979 that greenhouse warming was potentially serious. The panel said that they had rather high confidence that a doubling of CO₂ would warm up Earth by about 3 °C, plus or minus 50%: in other words, 1.5–4.5 °C. Because of the complexities of the climate system, subsequent work has been unable to narrow the range. But at the time the range itself was regarded as highly uncertain; many scientists continued to doubt that there would be any greenhouse-effect global warming at all. Hansen and others predicted that the warming would rise above the noise level to become unequivocally visible sometime around the start of the twenty-first century.

Scientists had sought a single master key to climate, but now they were coming to understand that climate is an intricate system responding to many influences. Volcanic eruptions and solar variations were still plausible causes of change, and some argued these would swamp any effects of human activities. Subtle changes in Earth's orbit could also make a difference. Studies of ancient climates, as revealed in cores from the deep sea floor, showed that minor astronomical cycles (calculated in the 1930s by Milutin Milankovitch) had set the timing of the ice ages. To the surprise of many, the climate was apparently so delicately balanced that almost any small perturbation might set off a great shift. According to the new 'chaos' theories, a shift in such a system might be sudden and irreversible. Support for the idea came from ice cores arduously drilled from the Greenland and Antarctic ice sheets. They showed large and disconcertingly abrupt regional temperature jumps in the past, taking not centuries but mere decades.

Computer models confirmed that such severe climate shifts were possible, for example if greenhouse warming caused

a change in the pattern of ocean circulation. Even without that, experts predicted that warming would bring a risk of greater heat waves and droughts, stormy rains and floods, rising sea level, and other harms. However, the modelers had to make many arbitrary assumptions about clouds and the like, and some reputable scientists continued to dispute the reliability of the results.

One unexpected discovery was that the concentrations of certain greenhouse gases such as methane were rising fast. Trace gases derived from human activities were significantly blocking bands of the infrared that had formerly been transparent. According to the calculations published by a group under Veerabhadran Ramanathan in 1980, the cumulative effects could bring on global warming twice as fast as had been expected. Moreover, by 1980 laborious compilations of average global temperatures showed that these had begun to rise again. International panels of scientists began to warn that the world should take active steps to restrain fossil fuel emissions.

Concerns were sharpened by new evidence from the Greenland and Antarctic ice caps. The long cylinders of ice extracted by drillers contained tiny bubbles with samples of ancient air – by good fortune there was this one thing on the planet that preserved CO₂ intact. In 1980, a team published findings that were definite, unexpected, and momentous. In the depths of the last ice age, the concentration of CO₂ in the atmosphere had been as much as 50% lower than in our own warmer times. (These Greenland measurements were later called into question, but the dramatically lower ice-age level was quickly confirmed by other studies.) Pushing forward, by 1985, a French-Soviet drilling team at Vostok Station in central Antarctica produced an ice core 2 km long that carried a 150 000-year record, a complete ice age cycle of warmth, cold, and warmth. They found that the concentration of atmospheric CO₂ had gone up and down in remarkably close step with temperature. These findings marked a turning point, convincing many scientists that greenhouse warming must be taken seriously.

The scientists' worries first caught wide public attention in the summer of 1988, which was the hottest on record till then. (Most years since were hotter.) But the many scientific uncertainties, and the sheer complexity of climate, gave space for a vehement debate. Individuals who opposed government restraints on fossil fuels argued, for example, that the warming seen so far was caused by a coincident rise in solar activity. However, solar activity subsequently leveled off and then declined, but the planet continued to warm up.

In 1988, the world's governments created a novel institution, the Intergovernmental Panel on Climate Change (IPCC), to give them the most reliable possible advice. Following years of discussion among all the world's climate experts, any IPCC conclusions would have to be approved by a consensus of officials appointed by all the world's governments. During the 1990s, the scientists worked through a large number of new studies, notably a proliferation of improved computer models. These now included computation of realistic ocean circulation and the effects of aerosol emissions. By 2001, the modelers had simulated the detailed pattern of geographical and vertical

distribution of atmospheric heating expected from greenhouse warming. The pattern of change was different from the patterns that other influences (for example, changes in solar output) would produce. The computed greenhouse-effect 'signature' roughly matched the actual observational record of recent decades. Warming was greatest in the Arctic, for example, while the stratosphere was cooling as predicted.

Paleoclimate studies were also eloquent. The data from ice cores were reinforced by studies going back hundreds of millions of years. These studies confirmed, by wholly independent means, the computer modelers' finding that a doubling of CO₂ went along with a rise of mean global temperature of 3 °C, give or take a degree or two. Meanwhile, a 1999 reconstruction of a millennium of Northern Hemisphere temperatures by Michael Mann and colleagues showed that the warming of recent decades markedly exceeded anything reliably reported in the historical past. (This 'hockey stick' reconstruction came under severe attack, but the basic finding was confirmed by subsequent studies.)

In 2001, the IPCC managed to establish a meaningful consensus, phrased so cautiously that scarcely any expert dissented. The panel announced that although the climate system was so complex that scientists would never reach complete certainty, it was much more likely than not that our civilization faced severe global warming. At this point, scientists knew the most important things about how the climate could change during the twenty-first century. How the climate actually would change now depended chiefly on what policies humanity would adopt to restrain its emissions.

After 2001, improved computer models and an abundance of data of many kinds strengthened the conclusion that human emissions were very likely to be a main cause of the recent global warming. In 2007, the IPCC warned that, depending on what policies people adopted for emissions, by the end of the twenty-first century, one could expect the planet's average temperature to rise anywhere between about 1.4 and 6.5 °C. Although only a small fraction of this warming had happened so far, the predicted effects were already visible in some regions. The impacts were coming sooner and more severely than expected: more deadly heat waves, worse droughts and floods, and the migration or decline of sensitive species. If the emissions are not restricted, the panel warned that in coming centuries the seas would rise by meters to drown coastal cities and entire ecosystems on which civilization depended would be impoverished.

Intergovernmental Panel on Climate Change

KE Trenberth, National Center for Atmospheric Research, Boulder, CO, USA

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

An outline is given of the IPCC and its role in helping to lay out options and consequences of actions or lack thereof related to anthropogenic climate change. A description is provided of how the IPCC is set up and functions, the scientific assessment process, who participates, and the intergovernmental linkages, all of which lead to the IPCC reports every 5–7 years. The procedures are designed to provide policy relevant but not policy prescriptive scientific advice to policy makers and the public. The main findings are briefly described along with the recent controversy involving IPCC.

In 2007, the Fourth Assessment Report of the Intergovernmental Panel on Climate Change (IPCC), known as AR4, clearly stated that 'Warming of the climate system is unequivocal' and it is 'very likely' due to human activities. Later in 2007, the IPCC won the Nobel Peace Prize, jointly with Al Gore Jr. 'for their efforts to build up and disseminate greater knowledge about man-made climate change and to lay the foundations for the measures that are needed to counteract such change.' This article describes the IPCC and its role in society and politics.

The IPCC is an international organization that includes a panel of governments and a body of scientists from around the world convened by the United Nations jointly under the United Nations Environment Programme and the World Meteorological Organization (WMO) and initiated in 1988. Its mandate is to provide policy makers with an objective assessment of the scientific and technical information available about climate change, its environmental and socioeconomic impacts, and possible response options. The IPCC reports on all aspects of the science of global climate and the effects of human activities on climate in particular. Major assessments were made in 1990, 1995, 2001, and 2007 and are called the First, Second, and Third Assessment Reports (FAR, SAR, and

TAR) and AR4 for the Fourth Assessment Report. The Fifth Assessment report (AR5) was released in 2013.

Each new IPCC report reviews all the published literature over the previous 5–7 years and assesses the state of knowledge, while trying to reconcile disparate claims and resolve discrepancies, and document uncertainties. There is a 'technical summary' and a short 'summary for policy makers' (SPM) and the volume from each of the three working groups (WGs) has tended to run to about 1000 pages or so.

WG I deals with how the climate has changed and the possible causes. It considers how the climate system responds to various agents of change and the ability to model the processes involved as well as the performance of the whole system. It further seeks to attribute recent changes to the possible various causes, including the human influences, and thus it goes on to make projections for the future. WG II deals with impacts of climate change, vulnerability, and options for adaptation to such changes, and WG III deals with options for mitigating and slowing the climate change, including possible policy options. Each WG has two coauthors, one from a developing country and one from a developed one. Each WG is staffed by a small Technical Support Unit that is hosted by one of the coauthors of the WG.

The IPCC also includes a task force on National Greenhouse Gas Inventories (TFI) to oversee the National Greenhouse Gas Inventories Programme and to develop and refine an internationally agreed methodology and software for the calculation and reporting of national greenhouse gas emissions and removals and to encourage its use by parties of the United Nations Framework Convention on Climate Change (UNFCCC). The task group on Data and Scenario Support for Impacts and Climate Analysis was established to facilitate cooperation between the climate modeling and climate impacts assessment communities by increasing the availability of climate change-related data and scenarios for climate analysis and impacts, adaptation, vulnerability, and mitigation research.

The IPCC is an intergovernmental body. It is open to all member countries of the United Nations and WMO. Currently, 194 countries are members of the IPCC. Governments participate in the review process and the plenary sessions, where main decisions about the IPCC work program are taken and reports are accepted, adopted, and approved. The IPCC bureau members, including the Chair, are also elected by governments during the plenary sessions. The IPCC Secretariat in Geneva coordinates all the IPCC work and liaises with governments. Thousands of scientists from all over the world contribute to the work of the IPCC on a voluntary basis.

The IPCC bureau comprises the IPCC chair, the IPCC vice-chairs, the co-chairs and vice-chairs of the WGs, and the co-chairs of the task force. The IPCC bureau is chaired by the IPCC chair. The purpose of the bureau is to provide guidance to the panel on the scientific and technical aspects of its work, to advise on related management and strategic issues, and to take decisions on specific issues within its mandate, in accordance with the principles governing IPCC work. Coordinating lead authors (CLAs) and lead authors (LAs) are selected by the relevant WG or task force bureau from those experts cited in nominations provided by governments and participating organizations, and other experts as appropriate, known through their publications and works, and taking into account both geography and gender. None of them is paid by the IPCC.

The IPCC starts a new assessment with a scoping process among experts, which leads to the proposed general outline of a report, highlighting also new features and cross-cutting matters. Policy makers and other users of IPCC reports are consulted in order to identify the key policy-relevant issues along with experienced scientists who can attest to the state and capabilities of the science. The outlines are subject to formal approval by the panel before work begins.

CLAs take overall responsibility for coordinating a major section of a report and the chapter that they are responsible for. For the first four reports, there were usually two CLAs per chapter. LAs work in teams to produce the content of the chapter. LAs may enlist contributing authors who provide additional technical information on specific subjects covered by the chapter. LAs are responsible for the production of designated sections of chapters. The essence of the LA task is to synthesize the scientific, technical, and socioeconomic information available in peer-reviewed and internationally available literature and in selected non-peer-reviewed literature.

Along with comprehensive assessment reports, the IPCC has produced several special reports and technical papers on topics of interest, as well as methodology reports. Many of these reports are prepared in response to requests from the UNFCCC or from other international organizations and conventions.

Each WG is made up of participants from the United Nations countries, and for the 2007 AR4 assessment, there were over 450 LAs, 800 contributing authors, and over 2500 reviewers from over 130 countries who provided over 90 000 review comments. The IPCC process is very open. Two major reviews are carried out in producing the report, a first review by experts and a second review by experts and governments. Climate 'skeptics' can and do participate, some as authors. All comments are responded to in writing and result in many changes in the report. The process is overseen by two or more review editors for each chapter.

As an example for the AR4 in WG I, there were 11 chapters and the report was 996 pages plus supplementary material

online. There were 140 LAs, hundreds of contributors, and two or three review editors for each chapter (26). There were also over 700 reviewers. For example, for Chapter 3 on observations, the CLAs were Kevin E. Trenberth and Philip D. Jones; there were 10 other LAs and 66 contributing authors. The published chapter ran to 101 pages plus online supplementary material, 47 figures (126 panels), 8 tables, and 863 references, making it the longest chapter in the report. In the expert scientific review, there were 2231 comments and another 1270 comments in governmental review, for a total of 3501 comments. Every comment and the writer were entered into a huge spreadsheet along with the response and actions taken in terms of changing the text.

Summaries for policy makers are prepared after the first expert review rather than concurrently with the main reports. They undergo one round of expert and government review. Each point undergoes not only the careful scrutiny of the scientists but also government officials and nongovernmental organizations. A second opportunity for comments by governments takes place as input to the approval process. The SPM is then approved line-by-line by governments in a major meeting, which takes place over 3 or 4 days. Those participating include government representatives (typically more than 120 countries are present), several nongovernmental organizations as observers, and typically 40–50 scientists. Simultaneous translation occurs throughout the meeting into English, French, Spanish, Russian, Chinese, and Arabic, per UN practice.

United Nations rules require a unanimous consensus to be sought. Negotiations occur over wording to ensure accuracy, balance, clarity of message, and relevance to understanding and policy. The strength is that it is a consensus report but the process also makes it a conservative report. The rationale is that the scientists determine what can be said, but the governments determine how it can best be said.

The IPCC process is dependent on the good will of the participants in producing a balanced assessment. However, by the time of the SAR, it appeared that there were attempts to blunt, and perhaps obfuscate, the messages in the report by certain nations. This led to protracted debates over wording on even bland and what should be uncontroversial text. The result was that the schedule of the meetings quickly became disrupted so that extra evening sessions were scheduled. During the limited breaks that did occur, authors of the report worked with delegates in side meetings to craft revised text for submission to the plenary. In many ways the meeting became one of endurance. In spite of these trials and tribulations, the result is a reasonably balanced consensus summary. However, the SPM did tend to grow in size relative to the initial draft length during the course of the meeting and usually became more technical than desirable.

The role of the IPCC is to provide policy relevant but not policy prescriptive scientific advice to policy makers and the general public. IPCC scientists, with all kinds of value systems, ethnic backgrounds, and from different countries, gather together to produce the best consensus description of what they jointly understand and with appropriate statements about confidence and uncertainty. The strength of the IPCC report is not just the solid scientific credentials but also the open process by which it is created.

Some Findings

The scientific evidence brought up by the first IPCC Assessment Report of 1990 unveiled the importance of climate change as a topic deserving a political platform among countries to tackle its consequences. It therefore played a significant role in leading to the creation of the UNFCCC, the key international treaty to reduce global warming and cope with the consequences of climate change. The UNFCCC was ratified in 1994 by 194 countries.

The SAR was the time when the IPCC first attracted more focused attention of policy makers in a major way when the statement coming out of the intergovernmental meeting and the SPM was ‘The balance of evidence suggests a discernible human influence on global climate.’ This statement was carefully crafted after much debate and compromise. The SAR provided key input into the adoption of the Kyoto Protocol in 1997. The Kyoto Protocol was finally ratified in February 2005 by 164 countries, and eventually by Australia, but not by the United States.

In the TAR, WG I presented an improved understanding of climate processes, forcing agents, and feedback and addressed the question of human influence on climate. Since the SAR, the evidence became much stronger – from the continuing record warmth, the improved paleorecord that provides context, improved modeling and simulation of the past climate and improved statistical analysis. Projections of future climate were based on new scenarios and a wider range of models. WG II updated impacts, vulnerabilities, coping strategies and adaptation, and implications for sustainable development. WG III assessed mitigation options, their costs and co-benefits as well as barriers, opportunities, and policy instruments. It also placed climate change mitigation in the context of sustainable development. The most contentious paragraph in the TAR WG I SPM was the concluding one on attribution. After much debate the following was carefully crafted in the summary statement for the TAR: “There is new and stronger evidence that most of the warming observed over the last 50 years is attributable to human activities.”

In AR4, WG I provided a new knowledge on human and natural drivers of climate, a detailed assessment of past paleoclimate changes and causes, and stronger evidence on attribution of climate change; it also included some regional aspects and observations of trends in other variables such as ocean warming, temperature extremes, and wind patterns. WG II further assessed observational evidence of impacts of climate changes and identified vulnerable places and people. Projections were made concerning impacts of future warming trends, taking into consideration different possible developments and stresses from other effects of global change. WG III further evaluated emissions trends, mitigation options, and how stabilization of greenhouse gas concentrations in the atmosphere might be achieved, along with associated costs in the near and longer term. Sustainable development policies were considered along with the relationship between mitigation and adaptation. A more consistent evaluation of uncertainty and risk was attempted. AR4 WG I carefully stated that “Warming of the climate system is unequivocal as is now evident from observations of increases in global average air and ocean temperatures, widespread melting of snow and ice, and rising

global average sea level” and Most of the observed increase in global average temperatures since the mid-20th century is very likely due to the observed increase in anthropogenic greenhouse gas concentrations. Here ‘very likely’ is deemed to mean more than 90% probability of occurrence.

AR5 will put greater emphasis on assessing the socioeconomic aspects of climate change and implications for sustainable development, risk management, and the framing of a response through both adaptation and mitigation. It will aim to provide more detailed information on regions, including on climate phenomena such as monsoons and El Niño.

Controversy

Following the SAR in 1995, a controversy broke out after completion of the report because of publicized charges (*Wall Street Journal*) that changes were made by the convening LA of Chapter 8, Dr. Ben Santer, to ‘deceive policy makers and the public into believing that the scientific evidence shows human activities are causing global warming.’ Santer indeed made changes in the chapter as instructed and as an outcome of the intergovernmental approval meeting and associated changes in the SPM. The charges were completely unfounded, but the lack of IPCC oversight of this process led to the introduction of review editors in subsequent reports.

Following the TAR, the main controversy centered on the paleoclimate reconstruction of northern hemisphere temperature for the last millennium that has the shape of an ice hockey stick with the blade as the upturn in the twentieth century. It has been used by some as a symbol of the human influence on climate. Dr. Michael Mann was the leader of the group that produced the ‘hockey stick’ and has come under considerable but unjustified criticism.

After the 2007 IPCC reports, in the lead up to the political Conference Of the Parties (COP) meeting in Copenhagen in December 2009 (COP-15), some controversies broke out that involved the IPCC. Disparagingly called ‘climate gate,’ some emails and personal information about individuals were illegally taken from the University of East Anglia through a hacking incident. Subsequently, there was selective publication of some of the stolen emails taken out of context and charges were made of data tampering and other wrongdoing. The material published was related to the work of the Climatic Research Unit and Professors Phil. Jones and Keith Briffa in particular. As Jones was a CLA of Chapter 3 of WG I in AR4 and both contributed to the chapter on paleoclimate, many of the emails involved IPCC matters and authors. There were several things in the emails that were obviously not for public consumption and possible abuses of the freedom of information act were revealed. Charges were brought against both Jones and Mann. Several official enquires in both the United Kingdom and the United States cleared them both of any wrongdoing.

The 2007 IPCC report itself has been scrutinized along with all of the comments and responses to the comments. Two minor errors have been found: both in WG II. These were on (1) Himalayan glaciers melt (correct in WG I) and (2) the area of the Netherlands below sea level. Unfortunately, these were played up and exaggerated in the media, and the IPCC was

slow to respond and did not handle the charges well by defending its processes.

Scientists have been found innocent of the charges made against them, and the basic science and all the main IPCC conclusions are unaffected. However, the criminals who stole the emails have not been brought to justice and those who misused the information and carried out the disinformation campaign were the real offenders. Unfortunately, their tactics have influenced the political process.

The adverse publicity concerning the IPCC raised concerns in some quarters regarding the continuing credibility of the IPCC assessments themselves and the processes and procedures underlying them and led to an investigation. In August 2010, the prestigious InterAcademy Council (representing scientific academies around the world) issued a report reviewing the procedures of the IPCC and made a number of recommendations for changes. They noted the need for the IPCC to update procedures, the need to have an executive committee to deal with issues such as minor corrections and to respond promptly to matters arising, to upgrade review oversight of reports, improve ways of communicating uncertainty, and improve communication in general.

Summary

The WG I findings might be summarized as follows. Climate changes have occurred in the past naturally, over decades to millennia for various reasons. However, humankind is performing a great geophysical experiment by modifying the Earth’s environment in various ways and changing the climate. Legitimate debates go on about the extent and rate of these changes, and what, if anything, to do about them but that the experiment is underway is not in doubt. The human-induced environmental changes of most relevance are in land use (e.g., farming, building cities), storage and use of water (dams, reservoirs, and irrigation), generation of heat, and combustion of fossil fuels. The latter, in particular, pollutes the atmosphere and alters the balance of radiation on Earth through both visible particulate pollution (called aerosols) and gases that change the composition of the atmosphere. The latter are referred to as greenhouse gases because they are relatively transparent to incoming solar radiation, while they absorb and reemit outgoing infrared radiation, thus creating a blanketing effect, which results in warming. Global warming and associated climate change are expected as a result and indeed are already occurring. The planet is unequivocally warming. Projections into the future indicate potentially dire consequences for ecosystems and human existence and well-being, sooner or later.

Given these findings, a key question is what should be done about them? The options include (1) do nothing, (2) mitigate or stop the problem, (3) adapt to the changes as they happen, or some combination of these. WG II deals with the first and the third option and WG III deals with option 2. Different value systems come into play in deciding what to do, and it is not the role of IPCC to decide, but it is the role of IPCC to lay out the options and likely consequences. Considerations include those of population growth, equity among developed and developing countries,

inter-generational equity, stewardship of the planet, vested interests, environmental concerns, and the precautionary principle (which suggests that it may be better to be safe than sorry). In rationally discussing options, it is helpful to recognize different points of view and that they are all legitimate. This problem is truly a global one, as the atmosphere is a global commons. It cannot be solved by one nation acting alone. IPCC helps to lay out the options and consequences of actions or lack of actions.

The IPCC website is <http://www.ipcc.ch>. Some of the material above comes from the IPCC website. A listing of IPCC procedures is at http://www.ipcc.ch/organization/organization_procedures.shtml#.T9Ipk5iwWP8.

Nuclear Winter

A Robock, Rutgers University, New Brunswick, NJ, USA

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

Nuclear winter is the term that describes the climatic effects of a nuclear war. Massive amounts of smoke from fires from burning cities and industrial areas would absorb sunlight, making it cold, dark, and dry at the Earth's surface and deplete ozone. A nuclear war between the USA and Russia today could produce nuclear winter, threatening the food supply for most of the planet. Even a nuclear war between new nuclear powers such as India and Pakistan could produce climate change unprecedented in recorded human history. The only way to eliminate the possibility of this climatic catastrophe is to eliminate the nuclear weapons.

Introduction

Nuclear weapons have existed for more than 65 years. The use of just one of these weapons would be horrible, as evidenced by Hiroshima or Nagasaki. For most of these 65 years, however, it is now known that mankind has possessed not just the means to destroy cities but the means to destroy the world, a 'Doomsday machine.' Although many people, several hundred million, would die from the immediate effects of nuclear weapons in a full-scale nuclear war, many more would die from the indirect effects, from starvation. Mass starvations in Africa, but without any outside help, now seem a more appropriate model for the world after nuclear war than Hiroshima or Nagasaki. More people could die in India or China from a nuclear war, even if no bombs are dropped there, than would die in the USA and Russia combined!

How could this possibly happen? Massive fires would be started by bombs dropped on cities and industrial targets, and the smoke from these fires would be so thick that it would block out the Sun for years. The resulting cold and dark at the Earth's surface was dubbed 'nuclear winter' by Richard Turco in 1983, because it would get as cold in the spring or summer as it gets in winter. Although these conclusions come from theoretical climate models, analogs on this planet and Mars give strong support to the theory.

Hiroshima

On 6 August 1945, a 15 kt nuclear bomb was dropped on Hiroshima, Japan, killing approximately 150 000 people. Many of these people died from the fires ignited by the bomb, which turned the city into a raging *inferno* – a firestorm – which pumped dense clouds of smoke high into the atmosphere. **Figure 1** shows the remains of the city. Where did all the buildings go? A significant fraction of them went up in smoke.

Many more people would have died if help had not been available immediately from outside the city in the form of medical care, food, water, and shelter. Three days later a 20 kt bomb was dropped on Nagasaki, also killing tens of thousands, and since then nuclear bombs have not been used in warfare.

Current Nuclear Arsenals

When nuclear winter theory first became known in the mid-1980s, at the height of the nuclear arms race, the world had

more than 50 000 nuclear weapons. Now, with the Cold War over, the USA and Russia are reducing their nuclear arsenals. Unfortunately, with more than 20 000 nuclear weapons still deployed in the world, there are still many more than would be necessary to produce nuclear winter. Even after the full implementation of the New Strategic Arms Reduction Treaty, signed on 8 April 2010 between the USA and Russia, with approximately 4000 nuclear weapons in the world by 2017 it will still be possible to produce nuclear winter. The total explosive power of the current nuclear arsenal is equal to about 5000 Mt (5 billion tons) of trinitrotoluene (TNT). 1 kt = 1000 t; 1 Mt = 1000 kt = 1 000 000 t. This large number becomes more meaningful when considered in perspective. There is the equivalent explosive power of almost a 1 t of TNT for each human on the face of the Earth. The Hiroshima bomb had an explosive power of 15 kt. This equals 0.015 Mt, which equals 0.0003% of the current global arsenal. If one Hiroshima-sized bomb had been dropped every *hour* from the end of World War II (WWII), it would have taken 38 years, until 1983, to use up the current arsenal!

The total explosive power of all bombs dropped in all of WWII, during which 50 000 000 people died, including Hiroshima and Nagasaki, was 3 Mt. The total explosive power of all bombs ever used in the history of the world in wars is 10 Mt. Yet, there is now available 500 times this explosive power in the world arsenals. This illustrates the enormity of the current potential to start fires.

While the American and Russian arsenals contain by far the majority of the world's nuclear weapons, there are seven more nuclear powers: France, Britain, China, India, Pakistan, Israel, and North Korea. A war between Pakistan and India could produce 5 Tg or more smoke, which would produce climate change unprecedented in recorded human history. It would not be nuclear winter, but it would be devastating.

How Nuclear Winter Could Be Produced

About one-third of the energy of a nuclear explosion is in the form of light or heat. It is like bringing the Sun to the Earth's surface for a brief moment. Anything close to the explosion will burst into flames. The assumption made in many nuclear winter scenarios is that anything receiving more than 10 calories per square centimeter per minute (about 7000 W m^{-2} – 20 times the average amount of energy received at the top of the Earth's

Figure 1 Hiroshima after a 15 kt bomb was dropped on 6 August 1945. The streets were cleaned before this picture was taken. Where have all the buildings gone? They burned in the resulting fire, pumping thick clouds of black smoke into the atmosphere. From US Air Force Photo Library, Bolling Air Force Base, Washington, DC.

atmosphere from the Sun) will burst into flames, and this was demonstrated in actual tests in Nevada before the atmospheric nuclear test ban.

Following the flash of light comes the blast wave (like thunder following lightning), which will break apart many structures and blow out the flames, but crumpled structures burn more easily and fires would be reignited by burning embers and electrical sparks. Imagine how easily a house would burn with open gas lines, or a filling station with gas pumps knocked over. In fact, there are many flammable sources of fuel for fires in cities, including buildings and their contents, trees, and even asphalt. Modern materials, such as plastics, not only burn with a sooty smoke, but also produce high levels of toxic chemicals.

The climatic, and hence lethal, effects of the use of nuclear weapons depend on the amount of smoke they would generate, and this depends on the targets. Nuclear targeting plans call for not only cities to be targeted but also industrial facilities such as oil refineries and wells. Forests around military targets would also provide fuel. All these targets together would produce clouds of black sooty smoke, which rise into the atmosphere. Less than 1% of current global nuclear arsenals would be enough to produce nuclear winter, if targeted at oil refineries.

The black smoke cloud would rise into the atmosphere and rapidly envelop the entire world. Absorption of sunlight would heat the cloud, cause it to rise, and induce winds, which would blow some of it into the Southern Hemisphere. Although about two-thirds of the smoke would be fairly rapidly cleansed from the atmosphere by rain and snow, about a third would remain for many years, with substantial amounts still in the stratosphere for at least a decade. Initial studies suggested that

the Earth's surface would become dark and cold, as cold in the summer as normal winter temperatures, hence the term 'nuclear winter.' Recent calculations with modern climate models have validated these early results. Intermediate results with less cooling led some critics to suggest that 'nuclear fall' would result and would in some way be more desirable than nuclear 'winter', but they were incorrect.

Climate Model Calculations

In 1982, the Swedish journal *AMBIO* commissioned a special issue on the environmental effects of nuclear war. They composed a scenario for a large-scale nuclear war in which 5000 Mt of weapons were dropped on targets in North America, Europe, and Asia, and invited different scientists to write papers on the effects on various parts of the environment. Paul Crutzen (winner of the Nobel Prize in Chemistry in 1995) and John Birks looked into the effects on atmospheric pollution. One of the most important constituents of air pollution near the Earth's surface is ozone, a major component of smog, which is formed by a photochemical reaction. Sunlight shining on a mixture of chemicals that would be released by explosions of industrial targets would produce ozone. To calculate the reaction rates they needed to know the amount of sunlight, so they did a quick calculation of the amount of smoke that would be produced from the fires that would burn after the bombs exploded. They were amazed to find that there would be so much smoke that virtually no sunlight would reach the surface! They also concluded that ozone would not be a major atmospheric pollutant near the Earth's surface.

This astounding result was quickly studied by climate researchers. During a 1-year period, scientists from many nations, including the USA and the Soviet Union, used many types of climate models to calculate how the Earth's climate system would respond to so much smoke in the atmosphere, and how the temperature, precipitation, and winds would change. The cooperative research between American and Russian scientists was a natural outgrowth of the close working relationship that had developed during the Soviet–American Scientific Exchange Program in climate research.

All the calculations came to the same conclusions. There would be so much smoke that virtually all the sunlight would be absorbed, and the surface of the Earth would become cold and dark for months, if not years. As climate models became more refined, and more and more details were added to the calculations, the precise amount of cooling moved up and down slightly, but no one could find a mechanism that would overcome the basic fact that light cannot go through thick clouds of smoke. Some critics argued that when more of the 'unknowns' were taken into consideration, this drastic result would be disproved, but unknowns, by definition, are *unknown*. While some previously unconsidered factors indeed lessened the cooling, others increased it, and the final consensus is not much different from the original calculations. In fact modern climate models, which incorporate a complete treatment of the ocean and simulate the atmosphere up through the mesosphere up to 80 km (50 miles), found that by absorbing sunlight the smoke would be lofted into the upper stratosphere and last for many years. The climatic effects of nuclear winter would last much longer than previously thought.

Not only would the surface air temperature be affected severely, but other drastic changes would also take place in the atmosphere. Climate model calculations show that precipitation would be reduced substantially over the continents in the years following the soot injection. The summer monsoon precipitation over Asia, the main source of rainfall for the entire year, would be virtually completely missing for years.

The fires would generate a substantial amount of air pollution, especially toxic chemicals (such as dioxins, furans, and polychlorinated biphenyls (PCBs)) from burning plastics and petrochemical facilities. Asbestos fibers would be injected into the air. In addition, radioactive fallout would be widespread, with some 'hotspots' having lethal levels.

The nuclear fireballs from large bombs penetrate up into the stratosphere. The intense heat produces NO and NO₂ (NO_x), which act as a catalyst to destroy ozone. Calculations show reductions of ozone in the stratosphere by as much as 50%, with the effects only gradually ameliorating over a period of years. A trend toward smaller nuclear weapons would lessen the number of fireballs reaching the stratosphere, but the changed atmospheric circulation would still take the NO_x up into the ozone layer and into the Southern Hemisphere, and the stratosphere would be so hot that ozone-destroying reactions would proceed much more rapidly, producing a global 'nuclear winter ozone hole' that would last for years. Even with the smoke, this would admit much more than the current amount of ultraviolet B (UV-B) radiation to the surface, affecting humans and other organisms.

The above results for the climate are for a nuclear war that would take place in the spring or summer. For one that would take place in the fall or winter, the immediate surface temperature effects would be less, since there is less sunlight to block out, but severe effects would still last for years.

Within the past 5 years, new results have shown that even a nuclear war between nuclear powers other than the USA and Russia superpowers could still produce so much smoke that summer temperatures around the world in food producing regions would plummet by several degrees, precipitation would go down, it would be darker, growing seasons would be shorter by weeks, and there would be much more UV-B radiation from ozone depletion. Reduced food production combined with panic in world food trade could spell starvation for a billion or more people. [Figure 2](#) shows the global average surface air temperature changes for 5 Tg smoke (war between India and Pakistan), and for two different smoke injections (50 and 150 Tg) that could result from a USA–Russia war.

Analogs

How can the extreme situations that have been calculated in theoretical models be investigated? The atmosphere cannot be brought into the laboratory and experiments cannot be performed on it. And the experiment cannot actually be performed in nature. Or it could be performed only once, and then it would be too late. However, other occurrences can be examined in the climate system to see if any similar situations have existed that would help learn about what would happen in the event of a nuclear winter. Situations that teach about parts of the interactions discussed above or for the global climate response can be studied, and the study need not have to be confined to this planet.

During WWII, firestorms were produced by conventional bombing in Dresden, Hamburg, Darmstadt, and Tokyo, and by nuclear bombing in Hiroshima and Nagasaki. Therefore, it is known that cities can burn, and in fact produce firestorms – superfires that spread far beyond the initial area of ignition and pump smoke high in the atmosphere. Kurt Vonnegut was a prisoner of war in Dresden during the fire there and in his book *Slaughterhouse 5* he described his experience:

He was down in the meat locker on the night that Dresden was destroyed. There were sounds like giant footsteps above. Those were sticks of high-explosive bombs. The giants walked and walked...

So it goes.

A guard would go to the head of the stairs every so often to see what it was like outside, then he would come down and whisper to the other guards. There was a firestorm out there. Dresden was one big flame. The one flame ate everything that was organic, everything that would burn.

It wasn't safe to come out of the shelter until noon the next day. When the Americans and their guards did come out, the sky was black with smoke. The sun was an angry little pinhead. Dresden was like the moon now, nothing but minerals. The stones were hot. Everybody else in the neighborhood was dead.

So it goes.

Figure 2 Global average surface air temperature change from the 5 Tg (red), 50 Tg (green), and 150 Tg (brown) cases in the context of the climate change of the past 125 years. Observations are from the National Aeronautics and Space Administration Goddard Institute for Space Studies analysis. Reproduced from Hansen et al. (2001); updated at <http://data.giss.nasa.gov/gistemp/2005/>. Figure 8 from Robock, A., Oman, L., Stenchikov, G.L., 2007b. Nuclear winter revisited with a modern climate model and current nuclear arsenals: Still catastrophic consequences. *Journal of Geophysical Research* 112: doi:10.1029/2006JD008235. With permission from ©American Geophysical Union.

So even one day later, the sky was still so full of the smoke that it almost completely blocked the Sun, and this was from 'conventional' bombing of only one city.

The diurnal cycle (day and night) provides a good analog. Imagine if the Sun did not rise tomorrow, if tonight were followed by another night followed by another night. This would be the situation under thick clouds of smoke in plumes downwind from major fires. It is easy to see how, even in the summer, temperatures could rapidly plummet to below freezing. The seasonal cycle analog, as already mentioned, has given the term, 'nuclear winter.'

Sixty-five million years ago an asteroid or comet smashed into the Earth producing a mass extinction of species. The best-known group of animals that disappeared at that time was the dinosaurs, but in addition, every land animal larger than a cat died and most of the plant species disappeared. In addition to a global dust cloud that blocked out the sunlight producing cold and dark conditions, there were continent-scale forest fires that also produced a thick smoke layer in the atmosphere, exactly what has been proposed for the nuclear winter.

Periodically, clouds of dust are blown up from the Sahara desert and transported all the way across the Atlantic Ocean. From this it is learned that dust particles in the troposphere (the lowest atmospheric layer, from the surface up to 8–18 km) can be spread large distances around the world. It has been observed that under Saharan dust clouds it is colder and there are fewer water clouds and less rain. This suggests a similar reaction to nuclear soot and dust.

There have been large forest fires in recent history, too, although not as large as those implicated in the extinction of the dinosaurs. These can be studied to learn about the properties of the smoke particles and how they affect light and heat radiation going through them. In September 1950 a giant forest fire raged in Western Canada for a week. A week later the smoke cloud covered the Eastern USA and a week after that it

was seen over Europe. Again how far particles can be transported by the wind before getting washed out of the atmosphere is seen. When the smoke was over Washington, DC, weather forecasts for high temperature were as much as 6 °C too high. The actual temperatures were 6 °C lower than were forecast because of the sunlight blocked by the smoke. Even in late September, when the Sun is not very intense, large surface temperature effects can result from a smoke cloud in the atmosphere, one that is much less thick than that calculated for nuclear winter.

This anecdotal report was confirmed in more recent studies that found surface cooling of 2–4 °C in the Midwestern USA under smoke clouds generated by forest fires in British Columbia, Canada, in 1982, and more than that produced by the September, 1988 forest fires in Yellowstone Park. The May 1987 forest fires in Northern China, and more recent ones in Australia and Canada, produced thick smoke clouds that rose all the way into the stratosphere where they resided for a long time, just as predicted by the computer models discussed in the previous section. In a nuclear winter situation, the smoke from burning cities and industrial facilities is expected to be thicker and blacker than forest fire smoke, producing even more cooling.

When the US Mariner 9 spacecraft first flew by Mars to take high-resolution pictures of the surface, the Northern Hemisphere of Mars was covered by a thick cloud of dust. (Mars has an atmosphere, too, but much thinner than the Earth's.) A few weeks later, the entire Martian globe was covered by this dust cloud. The heating of the atmosphere caused by the dust cloud in one hemisphere induced a circulation that transported the dust later into the other hemisphere. This same effect is part of the nuclear winter scenario and implies that regions far removed from the conflict would experience climate changes.

Volcanic eruptions provide several examples that can teach about nuclear winter. Clouds of volcanic dust and sulfuric acid

droplets that get injected into the stratosphere (the layer above the troposphere, where there is no weather and no rain to wash out the particles) have been observed to be spread completely around the globe in 3 weeks and remain for several years. This is the same fate postulated for nuclear smoke that either gets initially injected into the stratosphere or is lofted there by solar heating. Large volcanic eruptions can produce dust clouds in the troposphere immediately after the eruptions. Large surface temperature changes have been observed under these tropospheric volcanic dust clouds following the 1883 Krakatau, 1980 Mt St Helens, and 1991 Pinatubo eruptions in a manner similar to the effects of forest fire smoke.

The long-lasting stratospheric dust clouds also have been observed to produce global climate changes for several years following large volcanic eruptions. One of the largest in recent memory was the eruption of Tambora in 1815, which was followed by such cold weather during the following summer that 1816 has become known as the 'Year Without a Summer.' That summer the famous poet Lord Byron lived by the shore of Lake Geneva, Switzerland, next door to his friends, Percy Bysshe Shelley and his young 18-year-old bride Mary. The weather was so cold and gloomy that they had a contest to see who could write the best ghost story, and Mary Shelley won by writing *Frankenstein*, which begins and ends with frigid images of the monster climbing over ice floes. Byron himself was so depressed by the cold, gray weather that he wrote a poem called *Darkness* which begins:

I had a dream, which was not all a dream.
The bright sun was extinguish'd, and the stars
Did wander darkling in the eternal space,
Rayless, and pathless, and the icy earth
Swung blind and blackening in the moonless air;
Morn came and went—and came, and brought no day,
And men forgot their passions in the dread
Of this their desolation; and all hearts
Were chill'd into a selfish prayer for light:
And they did live by watchfires – and the thrones,
The palaces of crowned kings – the huts,
The habitations of all things which dwell,
Were burnt for beacons; cities were consumed,
And men were gather'd round their blazing homes
To look once more into each other's face; ...

This remarkable description of what the world might be like in a nuclear winter was inspired by a volcanic dust cloud much thinner than the cloud that would produce a nuclear winter!

Biological Consequences

The most important consequence of nuclear winter for humans is the disruption of food supplies. This could come about by two processes. One is the environmental disruptions that reduce or completely wipe out agricultural production. The other is the disruption of the distribution mechanisms. Not only would it be virtually impossible to grow food for several years after the nuclear holocaust, it would also be impossible to

obtain food from other countries. It is hard to imagine that countries with some food production (possibly Argentina, Australia, or New Zealand) would be willing to export it in such an uncertain international situation. For a regional nuclear war with less cooling, but still important disruptions of food production, these market disruptions could produce more shortages than the direct impacts on agriculture. In addition to the disruption of food, there would be many other stresses for any surviving people. These would include the lack of medical supplies and personnel, high levels of pollution and radioactivity, psychological stress, rampant diseases and epidemics, and enhanced UV-B radiation after the smoke clears.

There are many ways that agriculture is vulnerable to nuclear winter. The cold and the dark alone are sufficient to kill many crops. Superimposed on the average cooling would be large variations. During the summer of 1816 in New England, there were killing frosts in each summer month. Only 1 day with the temperatures below freezing is enough to kill rice crops. Colder temperatures mean shorter growing seasons and also slower maturation of crops, the combination results in much lower yields. Most of the grains that are grown in midlatitudes, such as corn, are actually of tropical origin, and will only grow in summerlike conditions. A study done in Canada shows that with summer temperatures only 3 °C below normal, wheat production would halt. Insufficient precipitation would also make agriculture difficult.

The tremendous productivity of the grain belt of the USA and Canada feeds not only those countries but also many in the rest of the world, including Russia, where normal climate variability often results in reduced harvests. This productivity is the result of modern farming techniques that allow less than 2% of the population to produce more than enough for the rest. In order to do this, tremendous energy subsidies are needed. Farmers depend on fuel for their machinery, fertilizer, and pesticides, none of which would be available or distributed in the aftermath of a war. Furthermore, insects have a higher tolerance for radiation and the stresses that would follow than do their predators, such as birds. Whatever might grow would be eaten by pests, already a significant problem in today's production. Also, the seeds that are in use were designed to yield high productivity assuming the current climate and inputs of chemicals and energy as discussed above. These seeds would not grow well in a radically altered growing environment. Mankind's dependence on technology is such that if every human in the USA went out to the fields to try to raise crops with manual labor, and if they knew what they were doing, and if they had enough food to eat, and if they were healthy, they still could not produce what is produced today.

Thus, most of the world's people are threatened with starvation following a nuclear war. The number that would survive depends on how much food is in storage, and how much could be produced locally. Studies of various countries around the world conclude that even with extremely optimistic assumptions of perfect distribution systems within countries, that each person who will survive becomes a vegetarian and eats the minimum needed for survival, and the others waste none of the food, that nations in Asia, Africa, and South America could only last 1–2 months. In many nations, people would be

reduced to a hunter/gatherer existence with nothing to hunt and precious little to gather.

The effects on health would add to the misery. Immune deficiencies can be produced by any of the following: burns and trauma, radioactivity, malnutrition, psychological stress, and UV-B radiation. All of these would be present for the survivors in the target nations. It would in some respects resemble an international epidemic of acquired immune deficiency syndrome (AIDS).

Pollution from dioxins, PCBs, asbestos, and other chemicals will make the air unhealthy to breathe. Severe psychological stress will prevent the survivors from making the efforts to continue to exist.

Would it be possible to survive in the USA or Europe? If you had a fallout shelter that was deep enough or far enough from the immediate effects of blast and fires, and if you stayed in it long enough so that you could safely come out (about a year considering the radioactivity and UV-B radiation) and if you had enough supplies to last you for that long and for several more years until you could produce more food, and if you did not go crazy from being cooped up in a hole in the ground, and if you had enough weapons to keep out all the other hungry people, then you could survive, if you call that surviving.

One might think that the ocean shore would be a good place to be because the temperatures would not fall as much, and there would be plenty of food to catch. Although the ocean would not cool very fast, the darkness would decimate the phytoplankton, which are at the base of the oceanic food chain. That, combined with toxic and radioactive pollution would severely limit the food sources in the oceans. Furthermore, the large temperature contrasts between the oceans and the land would produce strong storms that would make fishing difficult at best.

While it is important to point out the consequences of nuclear winter, it is also important to point out what will not be the consequences. Although extinction of mankind was not ruled out in initial studies by biologists, it now seems that this would not take place. Especially in Australia and New Zealand, humans would be sure to survive. Also, the Earth will not be plunged into an Ice Age. Ice sheets, which covered North America and Europe only 18 000 years ago and were more than 3 km thick, take many thousands of years to build up from annual snow layers, and the climatic disruptions would not last long enough to produce them. The oxygen consumption by the fires would be inconsequential, as would the effect on the atmospheric greenhouse by carbon dioxide production. The consequences of nuclear winter would be extreme enough without these additional effects, however.

Policy Implications

The suicidal nature of the use of nuclear weapons is one of the most important policy implications. If country A used enough weapons only against military targets to prevent country B from retaliating, in what is called a 'first strike,' the climatic consequences could be such that everyone in country A could die. Nuclear weapons, therefore, become an instrument of suicide and not an instrument of defense. A 'limited war' would not in itself be enough to trigger nuclear winter. Furthermore, once nuclear war is started, communications

would be so disrupted, by the smoke in the air and by the electromagnetic pulse (EMP) that would destroy all unprotected electronic gear, and people would be under so much stress, that it is considered unlikely that nuclear war could ever be limited.

Soon after the nuclear winter theory was discovered, Carl Sagan gave a briefing on the subject to Senators, Congressmen, and staff on Capitol Hill. He described how the smoke from burning cities and industrial areas after a nuclear war would be so thick as to block out so much sunlight that the Earth's surface would become so cold, dark, and dry for so long that agriculture would be impossible and most of the people in the world would starve to death. After the presentation, one of them called him aside and said, "Carl, if you think the mere threat of the end of the world is enough to change the way people in Washington and Moscow think, you clearly haven't spent enough time in either place!" Albert Einstein said, after nuclear weapons were invented, that their existence changed everything about the world, except for the way that we think, and thus we drift toward 'unparalleled catastrophe'.

Yet it does seem that nuclear winter has provided a context to reexamine all the existing policy assumptions about nuclear war. People are gradually changing the way they think. And it happened only because scientists have tried to warn the world of the dangers of current policies. The author feels that it is the responsibility of scientists, particularly those who use public money for their research, to warn society when they discover potential dangers, such as from nuclear winter or ozone depletion.

The world seems to be a much safer place now than it was in 1982 and 1983 when the first papers on nuclear winter were published. How much of this change was caused by the realization of the dangers of nuclear winter? Nobel Peace Prize winner Mikhail S Gorbachev, the prime architect of the current good East-West relations, said in an interview in 2000, "Models made by Russian and American scientists showed that a nuclear war would result in a nuclear winter that would be extremely destructive to all life on Earth; the knowledge of that was a great stimulus to us, to people of honor and morality, to act."

The Cold War is over, but many of the nuclear weapons produced during this period remain. The USA and Russia are very slowly reducing the numbers of weapons, but each still maintain an arsenal far larger than necessary to produce nuclear winter. No current leader of the USA or Russia would use nuclear weapons, but their existence alone makes the possibility of nuclear winter in the future possible if a crazy person or computer error or misunderstanding causes their use. The only solution is to reduce the number of weapons to a level that will still provide a deterrent, but will not create a nuclear winter should they ever be used. Reducing these numbers to a level below which they could produce a global climatic catastrophe, as Sagan was fond of saying, is a matter of elementary planetary hygiene. This number is less than a hundred, less than the number of weapons that Britain, France, and China have had in each of their arsenals for decades, a number that Israel, India, and Pakistan have chosen for their arsenals, and a number they have deemed more than sufficient to maintain a credible defense of their countries. This

is also the number Admiral Stansfield Turner, former Director of the CIA, argued for on other grounds in 1997. This problem must be solved so that there is the luxury of spending the time solving the problem of greenhouse warming and working toward nuclear abolition.

This article is dedicated to Carl Sagan, one of the leaders of nuclear winter research who died tragically in December 1996 at the young age of 62. Some of the ideas in his paper come from listening to his public talks on the issue. I thank him for so clearly expressing his concerns about this important issue.

Radiative–Convective Equilibrium Climate Models

NO Renno and X Huang, University of Michigan, Ann Arbor, MI, USA

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

Radiative–convective models and key results of simulations with them such as multiple climate equilibria and runaway greenhouse are described. These simple climate models are widely used not only to simulate the thermodynamic structure of the atmosphere of the Earth and other planets but also to study their sensitivity to changes in the concentration of greenhouse gases, convective processes, clouds, and the flux of incoming solar radiation.

Introduction

The terrestrial planets emit as much energy to space in the form of thermal radiation as they receive from the sun in the form of solar radiation. On Earth, the incident solar radiation is absorbed mostly at the surface, but it is also scattered and absorbed by atmospheric gases, aerosols, and clouds. The absorption of solar radiation, its redistribution by dynamic and radiative processes, and the emission of thermal radiation back to space determine the mean surface temperature and the mean vertical thermodynamic structure of the atmosphere. Radiative–convective models simulate these processes and give insights into their effects on the energy budget, the vertical structure, and the stability of planetary atmospheres.

Radiative–convective models are ideal for studying general principles and testing fundamental ideas. Their major drawback is the inability to calculate the feedbacks between the horizontal heat transports and the temperature structure from first principles. Radiative–convective models are widely used not only to simulate the thermodynamic structure of the atmosphere of the Earth and other planets but also to study their sensitivity to changes in the concentration of greenhouse gases, convective processes, clouds, and the flux of incoming solar radiation.

In the classical radiative–convective models developed in the 1960s, the atmosphere's water vapor mixing ratio is either fixed or diagnosed based on the climatological profile of relative humidity. In addition, these models use simple numerical procedures to parameterize the cumulus convection, the processes responsible for the distribution of water vapor into the atmosphere. Since water vapor is the most important greenhouse gas, it is desirable to explicitly calculate its content and vertical distribution. The radiative–convective models developed during the last 2 decades do this by explicitly calculating the hydrological cycle. Furthermore, they employ complex parameterization schemes similar to those that global climate models use to represent the cumulus convection and therefore to distribute the heat and water vapor and to produce the precipitation.

Radiative–Convective Models

Radiative–convective processes are described by the equations:

$$\frac{\partial \theta}{\partial t} = Q + R + F_\theta \quad [1]$$

$$\frac{\partial r}{\partial t} = C + F_r \quad [2]$$

integrated at each model pressure level. Time, t , and pressure, p , are independent variables. The prognostic variables are the potential temperature, θ , and the water vapor mixing ratio, r . Q in eqn [1] represents the heating by cumulus convection and large-scale condensation, while C in eqn [2] stands for the moisture source due to these two processes. These terms are calculated by parameterization schemes representing the net effects of cumulus convection and large-scale condensation. R in eqn [1] represents the net radiative heating. Radiation is calculated using models of wide range of complexity, depending on the specific goals of the simulation.

Vertical diffusion of heat and moisture are represented by

$$F_\theta = g \frac{\partial \tau_\theta}{\partial p} \quad [3]$$

$$F_r = g \frac{\partial \tau_r}{\partial p} \quad [4]$$

where τ_θ and τ_r represent the vertical fluxes of heat and water vapor. In the free atmosphere, these vertical fluxes are represented by

$$\tau_\theta = \rho^2 g k_\theta \frac{\partial \theta}{\partial p} \quad [5]$$

$$\tau_r = \rho^2 g k_r \frac{\partial r}{\partial p} \quad [6]$$

where ρ is the air density, g is the gravity acceleration, and k_θ and k_r are the coefficients of vertical diffusion of heat and water vapor. Surface fluxes are usually calculated using the bulk aerodynamic formulae:

$$\tau_\theta = \rho_a C_D |\mathbf{v}_a| (\theta_s - \theta_a) \quad [7]$$

$$\tau_r = \rho_a C_D |\mathbf{v}_a| (r_s - r_a) \quad [8]$$

where the subscripts 's' and 'a' refer to values at the surface and just above the surface, at a standard height referred to as the anemometer level. $C_D \approx 0.0025$ is the drag coefficient and $\mathbf{v}_a \approx 5 \text{ m s}^{-1}$ is the wind vector at the anemometer level. The radiative–convective equilibrium is not sensitive to the values of these arbitrary parameters because changing them simply changes the difference in potential temperature and water vapor mixing ratio between the surface and the anemometer level. The values of the potential temperature and water vapor

mixing ratio at the anemometer level are calculated by making the potential temperature and the water vapor mixing ratio constant from the model's lowest level to the anemometer level. This represents the effects of adiabatic mixing by either dry convection or turbulence.

A saturated surface with zero heat capacity and an infinite supply of moisture is usually used as the lower boundary condition because it speeds up the approach to equilibrium and does not affect the solution when the supply of water is not a limiting factor. In this case, the net energy flux into the surface is required to be zero at each instant.

Atmospheric Convection

A representation of the basic physical processes governing the transport of water vapor by cumulus convection is crucial for climate simulations because water vapor is the most important greenhouse gas. Manabe and his associates developed a simple parameterization for cumulus convection, referred to as convective adjustment, while pioneering the development of climate models in the 1960s. The Manabe scheme is based on the assumption that when the temperature lapse rate of a saturated area exceeds the moist adiabatic lapse rate, moist convection is always strong enough to mix the air moist adiabatically. Then, these mixed or adjusted layers are kept saturated and the excess water vapor falls out as rain. If a model layer is supersaturated, but the temperature lapse rate does not exceed the moist adiabatic, large-scale condensation occurs and the excess water vapor falls out as rain. After large-scale condensation, the layer is kept saturated, while its temperature is increased by the release of latent heat of condensation. This classical scheme is still widely used in radiative–convective models.

The comprehensive cumulus parameterization scheme developed by Emanuel three decades later lies in the other extreme of complexity by representing the detailed physics of cumulus convection. It assumes that the fundamental entities of cumulus convection are the subcloud-scale drafts rather than the cloud-scale circulations themselves. This scheme assumes that convection occurs whenever the environment is unstable to reversible adiabatic ascent of air parcels originating at any model level. It assumes that vertical transports of heat and water vapor are accomplished by saturated updrafts and downdrafts, by a single unsaturated downdraft driven by the evaporation of falling precipitation, and by the compensating subsidence in the cloud environment. The precipitation efficiencies of each saturated updraft, the fraction of the precipitation that falls through unsaturated air, and the rate of evaporation of falling precipitation are either specified or calculated based on physically based assumptions.

Multiple Climate Equilibria

Simulations with radiative–convective equilibrium climate models produce two linearly stable solutions. The first solution corresponds to an optically thin atmosphere. In this solution, solar radiation is mainly absorbed at the surface, and the bulk of the emission of radiation to space originates in the warm surface and low troposphere (the entropy flux is minimum).

This solution is stable to finite amplitude perturbations when the radiation emitted by an opaque version of the planet is larger than the absorbed solar radiation. The second equilibrium corresponds to an optically thick atmosphere. In this second solution, the atmosphere's opacity to infrared radiation is the largest. The bulk of the emission of radiation to space originates in the cold upper troposphere (the entropy flux is maximum) and the hydrological cycle is extremely active. **Figure 1** indicates that these two linearly stable solutions occur when the value of the net flux of solar radiation at the surface (the net forcing) is within the range for Earthlike planets, that is, the net forcing is between $F_1 \approx 275 \text{ W m}^{-2}$ and $F_3 \approx 295 \text{ W m}^{-2}$. These two solutions are separated by a linearly unstable solution marked by dashed lines in **Figure 1**.

Figure 1 shows that there is an asymptotic limit for the emission of thermal radiation by a convective moist planet in which the main atmospheric constituent is water vapor (or any infrared absorber whose atmospheric concentration is temperature dependent). This indicates that a runaway greenhouse might occur when the net solar forcing is above $F_2 \approx 290 \text{ W m}^{-2}$. When the solar forcing is above a larger, but model-dependent value $F_4 \approx 310 \text{ W m}^{-2}$, equilibrium is not possible and a runaway greenhouse always occurs. The runaway greenhouse is discussed below.

Runaway Greenhouse

The net flux of solar radiation into a planet with equilibrium climate must be balanced by the emission of thermal radiation to space. For a planet without atmosphere or for a hypothetical planet with an atmosphere without infrared absorber, this balance is always possible. In this case, increases in the surface temperature produce monotonic increases in the emission of thermal radiation by the planet's surface that leads to a unique equilibrium solution.

When the main atmospheric constituent is an infrared absorber whose atmospheric content is temperature dependent such as water vapor, increases in the surface temperature lead to

Figure 1 Sketch of the bifurcation for a moist atmosphere in radiative–convective equilibrium. The branches represented by a dashed line are linearly unstable.

an asymptotic value for the emission of thermal radiation to space (represented by F_2 in Figure 1). In this case, equilibrium might not be possible when the net heat input into the planet is larger than the value F_2 . In this case, increases in the surface temperature produce increases in the emission of thermal radiation by the planet up to a maximum value of the surface temperature (about 350 K in Figure 1) at which the emission of thermal radiation to space reaches a peak value. For temperatures above this value, increases in the surface temperature produce decreases in the emission of thermal radiation. This happens because increases in the atmosphere's optical thickness overcompensate for increases in the emission of thermal radiation by the warmer surface. Further increases in the surface temperature lead to increases in the concentration of the infrared absorber and produce the asymptotic value for the emission of thermal radiation.

The runaway greenhouse is caused by the fact that cumulus convection constrains the atmospheric temperature lapse rate to be approximately moist adiabatic and distributes water vapor vertically. When the atmosphere becomes opaque, thermal radiation is emitted to space from layers in the moist adiabatic atmosphere above the surface and therefore a region of constant temperature and opacity is produced. This decouples the emission of thermal radiation from the temperature of the surface and produces an asymptotic value for the emission of thermal radiation. When the net value of the incoming solar radiation is above this asymptotic value, a runaway greenhouse can occur.

Volcanoes: Role in Climate

A Robock, Rutgers University, New Brunswick, NJ, USA

Synopsis

Large volcanic eruptions inject sulfur gases into the stratosphere, which convert to sulfate aerosols with an e-folding residence time of about 1 year. The radiative and chemical effects of this aerosol cloud produce responses in the climate system. Volcanic eruptions produce global cooling, and are an important natural cause of interdecadal and interannual climate changes. Regional responses include winter warming of Northern Hemisphere (NH) continents following major tropical eruptions and weakening of summer Asian and African monsoons following tropical and NH high latitude eruptions. The volcanic cloud also produces stratospheric ozone depletion. Very large, but rare, eruptions, such as that of Toba 74 000 years ago, may have caused very large climate changes.

Introduction

Explosive volcanic eruptions affect climate by injecting gases and aerosol particles into the stratosphere. Only if the eruption cloud is rich in SO₂, will the eruption produce a long-lived cloud of sulfate aerosols that forms over the next few weeks. Otherwise, explosive eruptions that only produce large ash particles, such as the 1980 Mt. St. Helens eruption, can produce a large local weather perturbation but do not have long-lasting climatic effects. Some volcanoes, such as Kilauea and Etna, produce large quiescent tropospheric emissions of sulfate aerosols, but only if there is a dramatic change in these emissions will climate be changed. Stratospheric aerosol clouds last for several years, reflecting sunlight and cooling the surface. These clouds also absorb both solar (near infrared) and terrestrial radiation, heating the lower stratosphere. Volcanic aerosols also serve as surfaces for heterogeneous chemical reactions that destroy stratospheric ozone, which lowers ultraviolet (UV) absorption and reduces the radiative heating in the lower stratosphere, but the net effect is still heating. This also allows more UV radiation to reach the surface. As this chemical effect depends on the presence of anthropogenic chlorine, it has become important only in recent decades. Tropical eruptions produce asymmetric stratospheric heating, producing a stronger polar vortex and associated positive mode of the Arctic Oscillation in tropospheric circulation. This pattern is one of enhanced warm advection over Northern Hemisphere (NH) continents in winter, producing winter warming after large tropical eruptions. There is no evidence that volcanic eruptions can produce El Niños, but El Niño–Southern Oscillation (ENSO) variations must be considered when searching the climatic record for volcanic signals, as they have similar amplitudes and timescales.

There have been several large volcanic eruptions in the past 250 years (Table 1), and each has drawn attention to the atmospheric and potential climatic effects. The 1783 Laki eruption in Iceland produced large effects in Europe causing Benjamin Franklin, the United States ambassador to France, to publish the first paper on the subject in more than 1800 years. The 1815 Tambora eruption, combined with the effects of the unknown 1809 eruption, produced the ‘Year Without a Summer’ in 1816 and inspired *Frankenstein*, written by

Table 1 Major volcanic eruptions of the past 250 years

<i>Volcano</i>	<i>Year of eruption</i>

Mt. Pinatubo, Luzon, Philippines	1991

Mary Shelley on the shores of Lake Geneva, Switzerland, that summer. The 1883 Krakatau eruption was the largest explosion ever observed, and the sound wave was tracked on microbarographs for four complete circuits of the Earth, taking almost 2 days for one circuit. The Royal Society report on this eruption published 5 years later remains the most extensive report on the atmospheric effects of a volcanic eruption. The 1963 Agung eruption produced the largest stratospheric dust veil in more than 50 years in the Northern Hemisphere, and inspired many modern scientific studies. The subsequent 1982 El Chichón and 1991 Mt. Pinatubo eruptions produced very large stratospheric aerosol clouds and large climatic effects. Quantification of the size of these eruptions is difficult, as different measures reveal different information. For example, one could examine the total mass ejected, the explosiveness, or the sulfur input to the stratosphere.

Volcanic Emissions

Volcanic eruptions inject several different types of particles and gases into the atmosphere (Figure 1). These volatile inputs can be assessed based on measurements from active, but not explosive, eruptions, and remote sensing of the resulting

Figure 1 Schematic diagram of volcanic inputs to the atmosphere and their effects. Reproduced from Robock, A., 2000. Volcanic eruptions and climate [Plate 1]. Reviews of Geophysics 38: 191–219 [From which this article was condensed and updated], with permission from American Geophysical Union, copyright American Geophysical Union.

aerosol clouds from lidar, radiometers, and satellites. Several satellites routinely monitor SO_2 , allowing the direct measure of stratospheric injection of gases from eruptions and measure the resulting aerosol clouds.

The major component of volcanic eruptions is the matter which emerges as solid, lithic material, or solidifies into large particles, which are referred to as ash or tephra. These particles fall out of the atmosphere very rapidly, on timescales of minutes to a few days, and thus have no climatic impacts. When an eruption column still laden with these hot particles descends down the slopes of a volcano, this pyroclastic flow can be deadly to those unlucky enough to be at the base of the volcano. The destruction of Pompeii and Herculaneum after the AD 79 Vesuvius eruption is the most famous example.

Volcanic eruptions typically also emit gases, with H_2O , N_2 , and CO_2 being the most abundant. Over the lifetime of the Earth, these gases have been the main source of the planet's atmosphere and ocean, after the primitive atmosphere of hydrogen and helium was lost to space. The water has condensed into the oceans, the CO_2 has been changed by plants into O_2 or formed carbonates which sink to the ocean bottom, and some of the carbon has turned into fossil fuels. Of course, humans eat the plants and animals that eat the plants, drink the water, and breathe the oxygen, so each human is made of volcanic emissions. The atmosphere is now mainly

composed of N_2 (78%) and O_2 (21%), both of which had sources in volcanic emissions.

Of these abundant gases, both H_2O and CO_2 are important greenhouse gases, but their atmospheric concentrations are so large (even for CO_2 at only 392 ppm in 2011) that individual eruptions have a negligible effect on their concentrations and do not directly impact the greenhouse effect. Rather the most important climatic effect of explosive volcanic eruptions is through their emission of sulfur species to the stratosphere, mainly in the form of SO_2 , but possibly sometimes as H_2S . These sulfur species react with H_2O to form H_2SO_4 on a time-scale of weeks, and the resulting H_2SO_4 aerosols produce the dominant radiative effect from volcanic eruptions.

The 1982 El Chichón eruption injected 7 Mt of SO_2 into the atmosphere. There has not been a large stratospheric injection since 1991, when Mt. Pinatubo in the Philippines put about 20 Mt of SO_2 into the lower stratosphere. In 2008 Kasatochi (in the Aleutian Islands of Alaska), and in 2009 Mt. Sarychev (in the Russian Kamchatka Peninsula), and in 2011 Nabro (in Eritrea) each put about 1.5 Mt SO_2 into the lower stratosphere, but that was not enough to have any detectable climatic influence. The Eyjafjallajökull eruption in Iceland in 2010, while very disruptive of air traffic for weeks, had so little SO_2 , and with a short lifetime of a week or so in the troposphere, that it had no impact on climate.

Once injected into the stratosphere, the large aerosol particles and small ones being formed by the sulfur gases are rapidly transported around the globe by stratospheric winds. Observations after the 1883 Krakatau eruption showed that the aerosol cloud circled the globe in 2 weeks. Both the 1982 El Chichón cloud and the 1991 Pinatubo cloud circled the globe in 3 weeks. Although El Chichón (17° N) and Pinatubo (15° N) are separated by only 2° of latitude, their clouds, after only one circuit of the globe, ended up separated by 15° of latitude, with the Pinatubo cloud straddling the Equator and the El Chichón cloud extending approximately from the Equator to 30° N. Subsequent dispersion of a stratospheric volcanic cloud depends heavily on the particular distribution of winds at the time of eruption. For trying to reconstruct the effects of older eruptions, this factor adds a further complication, as the latitude of the volcano is not sufficient information.

Quiescent continuous volcanic emissions also add sulfates to the troposphere, but their lifetimes there are much shorter, although longer than anthropogenic sulfates as they are emitted from the sides of mountains rather than at the surface. The local pollution produced by the emission of the Kilauea crater on the Big Island of Hawaii is called 'vog' (volcanic fog). Global sulfur emission of volcanoes to the troposphere is about 14% of the total natural and anthropogenic emission, producing cooling at the surface. Only if there is a long-term trend in these emissions, will they be important for climate change; nevertheless, they must be considered when evaluating the effects of anthropogenic sulfate emissions.

Radiative Interactions and Climate Forcing

The major effect of a volcanic eruption on the climate system is the effect of the stratospheric cloud on solar radiation (Figure 1). Some of the radiation is scattered back to space, increasing the planetary *albedo* and cooling the Earth-atmosphere system. The sulfate aerosol particles (typical effective radius of 0.5 μm , about the same size as visible light) also forward scatter much of the solar radiation, reducing the direct solar beam, but increasing the brightness of the sky. After the 1991 Pinatubo eruption, the sky around the Sun appeared more white than blue because of this. Figure 2 illustrates this effect using observations from the Mauna Loa observatory in Hawaii. After the El Chichón eruption of 1982 and the Pinatubo eruption of 1991, the direct radiation was significantly reduced, but the diffuse radiation was enhanced by almost as much. Nevertheless, the volcanic aerosol clouds reduced the total radiation received at the surface. The El Chichón radiative effect at Hawaii was larger than that of Pinatubo, because its cloud was centered at the latitude of Hawaii, while only the edge of the larger Pinatubo cloud was monitored.

As the Sun sets, the yellow and red light (because Rayleigh scattering removes the shorter wavelengths in the process that produces the blue sky) is reflected from the bottom of stratospheric volcanic clouds, producing a characteristic yellow and red sky $1/2$ –1 h after the time of sunset (Figure 3). This effect has been used in the past to detect distant eruptions and to estimate the height of the aerosol cloud and its extent.

Climatic Impact of Volcanic Aerosols

Stratospheric aerosol clouds from volcanic eruptions cool the Earth's surface for several years, but produce winter warming over the continents in the NH. These and other effects are summarized in Table 2. Volcanic aerosols can be important causes of temperature changes for several years following large eruptions, and even on a 100-year timescale, they can be important when their cumulative effects are taken into account. This is very significant in analyzing the global warming problem, as the impacts of anthropogenic greenhouse gases and aerosols on climate must be evaluated against a background of continued natural forcing of the climate system from volcanic eruptions, solar variations, and internal random variations from land-atmosphere and ocean-atmosphere interactions. Individual large eruptions produce global or hemispheric cooling for 2 or 3 years, but the winter following a large tropical eruption is warmer over the NH continents, and this counterintuitive effect is due to a nonlinear response through atmospheric dynamics. The winter warming pattern is illustrated in Figure 4, which shows the global lower tropospheric temperature anomaly pattern for the NH winter of 1991–92, following the 1991 Mt. Pinatubo eruption. This pattern is closely correlated with the surface air temperature pattern where the data overlap, but the satellite data allow global coverage. The temperature over North America, Europe, and Siberia was much higher than normal, and that over Alaska, Greenland, the Middle East, and China was lower than normal. In fact, it was so cold that winter that it snowed in Jerusalem, a very unusual occurrence. Coral at the bottom of the Red Sea died that winter, because the water at the surface cooled and convectively mixed the entire depth of the water. The enhanced supply of nutrients produced anomalously large algal and phytoplankton blooms, which smothered the coral. This coral death had only happened before in winters following large volcanic eruptions.

At the tropopause, the boundary between the troposphere and the stratosphere, the strongest winds are found in the midlatitudes in the winter and are called the jet stream or polar vortex. The strength of the jet stream depends on the temperature difference (gradient) between the tropics and the polar region, which is largest in the winter when the polar regions cool. For a tropical eruption, the stratospheric heating from volcanic aerosols is larger in the tropics than in the high latitudes, producing an enhanced Pole-to-Equator temperature gradient, and in the NH winter, a stronger polar vortex and winter warming of NH continents. The stronger jet stream produces a characteristic wind pattern in the troposphere, which warms some regions and cools other ones. This pattern is called the 'Arctic Oscillation' and is the dominant mode of tropospheric variability. Tropical eruption clouds push the atmosphere into the positive phase of this natural variation. This indirect advective effect on temperature is stronger than the radiative cooling effect that dominates at lower latitudes and in the summer.

Because volcanic aerosols normally remain in the stratosphere for no more than 2 or 3 years, the radiative effect of volcanoes is interannual rather than interdecadal in scale. A series of volcanic eruptions could, however, raise the mean optical depth significantly over a longer period and thereby

Figure 2 Direct and diffuse broadband radiation measurements from the Mauna Loa observatory, measured with a tracking pyrheliometer and shade disk pyranometer on mornings with clear skies at solar zenith angle of 60°, equivalent to two relative air masses. The reduction of direct radiation and enhancement of diffuse radiation after the 1982 El Chichón and 1991 Pinatubo eruptions are clearly seen. Years on abscissa indicate January of that year. Volcanic eruptions and climate. *Reviews of Geophysics* 38: 191–219, with permission from American Geophysical Union, copyright American Geophysical Union.

give rise to a decadal-scale cooling. If a period of active volcanism ends for a significant period, such as for the 51-year period from 1912 to 1963 when global climate warmed, the adjustment of the climate system to no volcanic forcing could produce warming. Furthermore, it is possible that feedbacks involving ice and ocean, which act on longer timescales, could transform the short-term volcanic forcing into a longer term effect. As a result, the possible role of volcanoes in decadal-scale climate change remains unclear. However, the current century is the warmest of the past 10 centuries, with the previous several centuries called the Little Ice Age due to their coldness. Studies show that the interannual and interdecadal variations during this period were strongly affected by both volcanic eruptions and solar variations. The large warming of the past century, however, can only partially be explained by these natural causes, and in fact the second half of the twentieth century would have cooled due to volcanic eruptions if there had been no human emissions. The large warming of this

period can only be explained by including the effects of warming from anthropogenic greenhouse gases.

The Toba eruption 74 000 years ago, the largest volcanic eruption of the past 100 000 years, may have produced such large climate changes that it killed most humans on the planet, producing a genetic bottleneck such that all humans are descended from the same small number of survivors. This eruption on the island of Sumatra left a caldera about 86 km long and 30 km wide, with a large island inside, the resurgent block of the caldera. It erupted 1000 times more rock than the 1980 Mt. St. Helens eruption and injected approximately 100–300 times the amount of SO₂ into the stratosphere than the 1991 Pinatubo eruption. Depending on the assumptions about the properties of the resulting sulfate particles in the stratosphere, climate model simulations produce global average coolings of 3–15°C lasting for a decade or more. The larger values would have certainly been devastating for many species.

Figure 3 Volcanic sunset over Lake Mendota in Madison, Wisconsin, in July 1982, 3 months after the El Chichón eruption. Photograph by Alan Robock. Reproduced from Robock, A., 2000. Table 2 Effects of large explosive volcanic eruptions on climate

<i>Effect/mechanism</i>	<i>Begins</i>	<i>Duration</i>
Stratospheric warming <i>Stratospheric absorption of shortwave and longwave radiation</i>	1–3 months	1–2 years
Global cooling <i>Blockage of shortwave radiation</i>	Immediately	1–3 years
Global cooling from multiple eruptions <i>Blockage of shortwave radiation</i>	Immediately	Up to centuries
Winter warming of NH continents <i>Differential stratospheric heating, dynamical interaction with troposphere</i>	$\frac{1}{2}$ – $1\frac{1}{2}$ years	One or two winters
Reduced tropical precipitation <i>Blockage of shortwave radiation, reduced evaporation</i>	Immediately	~1 year
Reduction of Asian and African summer monsoon <i>Continental cooling, reduction of land–sea temperature contrast</i>	$\frac{1}{2}$ –1 year	One or two summers
Ozone depletion, enhanced UV <i>Dilution, heterogeneous chemistry on aerosols</i>	1 day	1–2 years

Ozone Impacts

Volcanic aerosols have the potential to change not only the radiative flux in the stratosphere, but also its chemistry. The most important chemical changes in the stratosphere are related to O_3 , which has significant effects on UV and longwave radiative fluxes. The reactions that produce and destroy O_3 depend on the UV flux, the temperature, and the presence of surfaces for

heterogeneous reactions, all of which are changed by volcanic aerosols. The heterogeneous chemistry responsible for the ozone hole over Antarctica in October each year occurs on polar stratospheric clouds of water or nitric acid, which only occur in the extremely cold isolated spring vortex in the Southern Hemisphere. Conditions in the NH are now changing and small O_3 depletions are being observed in spring there now, too. Reactions on polar stratospheric clouds make anthropogenic

Figure 4 Winter (Dec.–Jan.–Feb. (DJF)) lower tropospheric temperature anomalies (with the nonvolcanic period of 1984–90 used to calculate the mean) for the 1991–92 NH winter (DJF) following the 1991 Mt. Pinatubo eruption. This pattern is typical of that following all large tropical eruptions, with warming over North America, Europe, and Siberia, and cooling over Alaska, Greenland, the Middle East, and China. Data from Microwave Sounding Unit Channel 2R, updated courtesy of J Christy and now called Channel 2LT. Reproduced from Robock, A., 2000. Volcanic eruptions and climate. *Reviews of Geophysics* 38: 191–219 with permission from American Geophysical Union, copyright American Geophysical Union.

chlorine available for chemical destruction of O_3 . However, sulfate aerosols produced by volcanic eruptions can also provide these surfaces at lower latitudes and at all times of the year. In fact, after the 1991 Pinatubo eruption, column O_3 reduction of about 5% was observed, ranging from 2% in the tropics to 7% in the midlatitudes. Therefore, ozone depletion in the aerosol cloud is much larger and reaches 20%. The chemical ozone destruction is less effective in the tropics, but lifting of low ozone concentration layers with the aerosol cloud causes a fast decrease in ozone mixing ratio in the low latitudes.

Decrease of the ozone concentration following volcanic eruptions causes less UV absorption in stratosphere, which modifies the aerosol heating effect. The net effect of volcanic aerosols on the surface UV flux is to increase it, as the aerosols backscatter less UV than the subsequent O_3 depletion allows through. The reduced O_3 absorption of shortwave and longwave radiations reduces the stratospheric heating effect and can affect the winter warming phenomenon described above.

The volcanic effect on O_3 chemistry is a new phenomenon, depending on anthropogenic chlorine in the stratosphere. While there are no observations available, the 1963 Agung

eruption probably did not deplete O_3 , as there was little anthropogenic chlorine in the stratosphere. Due to the Montreal protocol and subsequent international agreements, chlorine concentration has peaked in the stratosphere and is now decreasing. Therefore, for the next few decades, large volcanic eruptions will have effects similar to Pinatubo, but after that, these O_3 effects will go away and volcanic eruptions will have a stronger effect on atmospheric circulation without the negative feedback produced by O_3 depletion.

Discussion

There is no evidence that volcanic eruptions produce El Niño events, but the climatic effects of El Niño and volcanic eruptions must be separated to understand the climatic response to each. It had been suggested that the simultaneous appearance of the large 1982–83 El Niño and the 1982 El Chichón eruption and the 1991 smaller El Niño and the Pinatubo eruption suggested a cause and effect relationship. However, no plausible mechanism has been suggested and further research into the oceanography of El

Niños shows that these started before the volcanic eruptions. Examination of the entire record of past El Niños and volcanic eruptions for the past two centuries also shows no significant correlation.

As volcanic eruptions and their subsequent climatic response represent a large perturbation to the climate system over a relatively short period, observations and the simulated model responses can serve as important analogs for understanding the climatic response to other perturbations. While the climatic response to explosive volcanic eruptions is a useful analog for some other climatic forcings, there are also limitations. For example, successful climate model simulations of the impact of one eruption can help validate models used for seasonal and interannual predictions. But they cannot test all the mechanisms involved in global warming over the next century, as long-term oceanic feedbacks are involved, which have a longer timescale than the response to individual volcanic eruptions. Theory tells that volcanic eruptions also will produce multidecadal impacts on oceanic heat content, but these impacts are small and cannot be separated from other factors in observations.

The theory of ‘nuclear winter,’ the climatic effects of a massive injection of soot aerosols into the atmosphere from fires following a global nuclear holocaust, includes upward injection of the aerosols to the stratosphere, rapid global dispersal of stratospheric aerosols, heating of the stratosphere, and cooling at the surface under this cloud. As this theory cannot be tested in the real world, volcanic eruptions provide analogs that support these aspects of the theory.

Recent suggestions of considering the use of geoengineering to control global climate through the creation of a permanent stratospheric aerosol cloud have used volcanic eruptions as an analog. While volcanic eruptions indeed cool the surface, they also produce ozone depletion and drought, thus raising cautions about the wisdom of such ideas. There are also many other reasons why geoengineering may be a bad idea.

Given the current understanding of the climatic impact of volcanic eruptions, it can be safely predicted that following the next large tropical eruption, there will be global cooling for about 2 years, and winter warming of the NH continents for 1 or 2 years. There will also be reduced summer monsoon precipitation over Asia and Africa. A large NH high latitude

eruption, if it occurs in spring or summer, will also produce a weak summer monsoon.

Synopsis

Cloud resolving models (CRMs) use more sophisticated and realistic representations of cloud microphysical processes, and they can reasonably well resolve the time evolution, structure, and life cycles of clouds and cloud systems (with sizes ranging from about 2 to 200 km). CRMs also allow for explicit interaction between clouds, outgoing longwave (cooling) and incoming solar (heating) radiation, and ocean and land surface processes. CRMs can be used to improve our understanding of: (1) convective organization, (2) cloud temperature and water vapor budgets, (3) convective momentum transport, (4) diurnal variation of precipitation processes, and (5) water and energy cycles.

Introduction

Numerical cloud models, which are based on the non-hydrostatic equations of motion, have been extensively applied to cloud-scale and mesoscale processes during the past five decades. Uncertainties stemming from convection that must be parameterized in (hydrostatic) large-scale models are mitigated by cloud models, which simulate the salient small-scale dynamics. Global weather and climate models will need to use the nonhydrostatic framework when their horizontal resolution gets to about 10 km, the theoretical limit of the hydrostatic approximation. This juncture will be reached within a decade.

The earliest kind of cloud model, the one-dimensional entraining bubble or plume that simply parameterizes the lateral entrainment of environmental air, was applied extensively to cloud seeding research, and is still used as a transport module for convective parameterization schemes. In the 1960s,

two-dimensional cloud models were developed to study cloud evolution in idealized environments. Three-dimensional cloud models, developed in the early 1970s, quantified the effects of wind shear on convection; for example, tropical squall lines, and midlatitude supercell thunderstorms associated with tornado genesis.

During the late 1970s and the early 1980s, cumulus ensemble models (also known as cloud-system resolving models) began to simulate the collective effects of moist convection on the large-scale environment, with emphasis on the Tropics. A primary objective was to improve cumulus parameterization, a quest that continues to this day. The effect of ice processes on cloud formation and evolution, stratiform rain processes, and their relation to convective rainfall were focal issues during this period, as was the organizing effect of environmental shear on mesoscale convective systems. The impact of radiative processes on cloud development was investigated in the late 1980s.

In the 1990s, cloud-system resolving models began to quantify interaction between the meso- and large-scale motion, cloud–chemistry interactions, cloud–climate interaction, and surface processes. An important application was in the design of satellite rainfall and latent heat retrieval algorithms for the Tropical Rainfall Measuring Mission (TRMM).

In the 2000s, cloud-system resolving models were used to study the aerosol–cloud and precipitation interactions and they were embedded into global models to study the water and energy cycles from local up to regional scale. **Table 1** summarizes the major highlights of model development over the past five decades.

Theoretical studies have advanced our basic knowledge of convection dynamics, and how convection interacts with the larger scales of motion. These studies enable the complexity of numerically simulated clouds to be reduced to first principles, which is essential to understand the role of moist processes in the Earth's weather and climate.

During the past generation, voluminous data on atmospheric convection accumulated from radar, instrumented aircraft, satellites, and rawinsonde measurements in field campaigns, enabled detailed model evaluations. Improved numerical methods have resulted in more accurate and computationally efficient dynamical cores. Improvements have been made in the parameterizations of microphysical processes, radiation and boundary layer effects, and turbulence; however, microphysical parameterizations remain a major source of uncertainty in all classes of atmospheric model.

Table 1 Highlights of cloud modeling development and application over the past five decades

<i>Major highlights</i>	
1960s	Loading, buoyancy, and entrainment
1970s	Slab- vs axis-symmetric model Cloud seeding
1980s	Cloud dynamics and warm rain Ensemble of clouds – cumulus parameterization Cloud interactions and mergers Ice processes Super cell dynamics Squall line Convective and stratiform interactions Wind shear and cool pool Gravity wave and density current Cloud radiation interaction
1990s	2D vs 3D Cloud-radiation quasi-equilibrium – climate variation implications Cloud transport and chemistry Diurnal variation of precipitation Gewex cloud system study (GCSS) Coupled with microwave radiative and radar model for satellite cloud retrieval (TRMM)
2000s	Land and ocean processes Multiscale interactions Energy and water cycle Cloud aerosol–chemistry interactions Cumulus parameterization improvements

In recent years, exponentially increasing computer power has extended cloud model integrations from hours to months, and the number of grid points from less than 1000 to more than 1 billion. Three-dimensional models are now more prevalent. Cloud models simulate the evolution, structure, and life cycle of cloud systems. They explicitly calculate interactions among clouds, longwave and solar radiation that are difficult, if not impossible, to observationally obtain. Much attention has been on precipitating cloud systems where the crucial meso-scale circulations are resolved by cloud-system resolving models. Observations provide both the initial conditions and data for model validation; model results provide statistical information useful for developing physically based parameterization for climate models and numerical weather prediction models.

Physical Processes in Cloud Models

Cloud-microphysical processes (phase changes of water and precipitation) must be parameterized in cloud models, as must atmospheric turbulence (dissipation of kinetic energy), turbulent processes at oceanic or terrestrial boundaries (latent and sensible heat fluxes into the atmosphere), and radiative transfer processes (complex in the presence of clouds).

Microphysics and Precipitation

Figure 1 depicts the widely used two-class liquid (cloud water and rain droplet) and three-class ice (cloud ice, snow, and graupel/hail) microphysics schemes. The shapes of liquid and ice particles are assumed to be spherical. The warm cloud microphysics assumes that the population of water particles is bimodal, consisting of small cloud droplets whose terminal velocity is minute compared to typical vertical air velocities, and large rain droplets that obey certain size distributions based

Figure 1 Representation of the three-class ice scheme used in the cloud model.

on limited observations. Condensation, evaporation, and autoconversion/collection processes (from small cloud droplets to large rain droplets) are parameterized. The ice microphysical schemes typically assume three classes of particle: small cloud ice, whose terminal velocity is also minute compared to typical vertical air velocities; snow, whose terminal velocity is about $1\text{--}3\text{ m s}^{-1}$; and large-sized graupel or hail with faster terminal velocities. Graupel has a lower density and a higher intercept (i.e., high number concentration). In contrast, hail has a high density and a small intercept. Graupel is representative of tropical clouds and hail of midlatitude clouds. More than 25 transfer processes between water vapor, liquid, and ice particles are included. These include the growth of ice crystals by riming, the aggregation of ice crystals, the formation of graupel and hail, the growth of graupel and hail by the collection of supercooled raindrops, the shedding of water drops from hail, the rapid growth of ice crystals in the presence of supercooled water, the melting of all forms of ice, and the deposition and sublimation of ice. Only large rain droplets, snow, and graupel/hail fall toward the ground as precipitation.

Only recently have some cloud-system resolving models adopted a two-moment four-class ice scheme that combines the main features of the three-class ice schemes by calculating the mixing ratios of both graupel and frozen drops/hail. Additional model variables include the number concentrations of all ice particles (small ice crystals, snow, graupel, and frozen drops), as well as the mixing ratios of liquid water for each of the precipitation ice species during wet growth and melting for purposes of accurate active and passive radiometric calculations.

In addition, explicit (spectral bin-microphysical) schemes have been developed for the study of cirrus development and cloud precipitation–aerosol interaction. The formulation of the explicit microphysical processes is based on solving stochastic kinetic equations for the size distribution functions of water droplets (cloud droplets and raindrops), and ice particles of different habits (columnar, platelike, dendrites, snowflakes, graupel, and frozen drops). Each type is described by a special size distribution function containing over 30 categories (bins). Nucleation (activation) processes are also based on the size distribution function for cloud condensation nuclei (also over 30 size categories). Because of the numerous interactions involved in spectral bin-microphysical schemes, computational domains are relatively small and simulation times short. These detailed microphysics calculations can provide a useful framework for evaluating and ultimately improving bulk microphysical schemes. Of particular interest in this regard is convectively generated cirrus, which affects the radiative properties of the tropical atmosphere.

Turbulence

Whilst large eddies are resolved in cloud models, eddies much smaller than the grid scale must be parameterized. An implicit assumption is that the small scales approximate to an inertial subrange where the energy spectrum is in statistical equilibrium, with an energy cascade from the resolved scales to the dissipation scales. The most sophisticated turbulence parameterization presently used is a third-moment closure. Typical cloud models used simple k -type (first-order) turbulence

closure or determine the coefficient k , diagnostically or prognostically, from the turbulence kinetic energy (TKE) equation (one-and-a-half order). In the prognostic TKE method, thermodynamic stability, deformation, shear stability, diffusion, dissipation, and transport of subgrid energy are included. In the diagnostic method, deformation and stability are used for computing the k coefficient.

Radiation

Emission and absorption by water vapor and cloud droplets are represented by two-stream long-wave radiative transfer schemes. Broadband methods for long-wave radiation combine the effects of reflection, emission, and transmission by cloud droplets and air molecules. The treatment of short-wave radiation is also based on broadband approximations. One key issue is how to parameterize cloud optical properties (optical thickness), especially in the presence of the ice phase, in view of the important impact of radiative heating and cooling profiles within clouds. Note that only limited observations are available upon which to base parameterizations for ice clouds.

The use of a fully explicit microphysics scheme (liquid and ice) and a fine horizontal resolution provides relatively realistic cloud optical properties, which are crucial for radiation budgets. With high spatial resolution, each atmospheric layer is considered either completely cloudy (overcast) or clear. No partial cloudiness is assumed.

Ocean Surface Processes

Two types of surface exchange (flux) schemes are typically used. The first is a simple bulk aerodynamic formula where the transfer coefficients for momentum, sensible heat, and latent heat fluxes are functions of wind speed only. The second type is more complex but, nevertheless, still a bulk approach. The transfer coefficients for momentum, sensible heat, and latent heat fluxes are based on the Monin–Obukhov similarity theory of the atmospheric surface layer. The parameters, such as the roughness lengths, are closely related to the sea surface characteristics and the turbulence characteristics. At very low wind speeds the similarity profile is singular, a problem addressed by adding a convective velocity to yield nonzero fluxes under windless conditions. The exchange coefficients in the simple bulk aerodynamic formula method and in the second bulk flux algorithm differ in two ways. First, in the lower wind speed regime (less than 4 m s^{-1}), the exchange coefficients in the complex bulk scheme increase with decreasing wind speed in order to account for the convective exchange at low wind speeds. Second, the coefficients in the simple bulk aerodynamic formula linearly increase with respect to the wind speed, but decrease if the wind speed is greater than 4 m s^{-1} in the more complex bulk schemes. These differences in the exchange coefficients can affect rainfall amounts and boundary layer structure.

Land Surface Processes

Detailed interactive land surface process models of the heterogeneous land surface (soil and vegetation) and adjacent near-surface atmosphere have recently been applied in cloud

models to study the effect of soil moisture distribution and atmospheric boundary conditions on cloud structure, rainfall, and soil moisture distribution. A land surface model usually has three elements: (1) a soil module that includes several water reservoirs, i.e., plant internal storage, dew/intercepted precipitation, surface material, a topsoil root layer, a subsoil root layer, and two deeper layers that regulate seasonal and interannual variability of the soil hydrology; (2) a surface slab of vegetation, litter, and other loose material that shades the soil and acts as the source for sensible heat flux, and intercepts precipitation and dew; and (3) the surface layer of the atmosphere (up to the lowest grid level of the model to which it is coupled), within which the fluxes of sensible heat and water vapor are calculated.

Modeling Tropical Convective Systems

While cloud models have been applied in numerous geographic locations, the most comprehensive studies have been conducted in the Tropics, often in association with observational field campaigns. Tropical convection affects the large-scale circulation of the atmosphere in many ways, including atmosphere–ocean coupling. The organization of tropical convection occurs across scales: cloud streets in the shallow trade-wind convection, cumulonimbus, cloud clusters, squall lines, tropical cyclone rainbands, multiscale convection in westerly wind bursts and intraseasonal oscillations, and enhanced convection in the intertropical convergence zone (i.e., the rising branch of the Hadley circulation) and in planetary-scale Walker circulation. Within the next few decades, computers will likely be powerful enough to resolve this multiscale hierarchy. Until this juncture many basic issues must be addressed in parameterization, including the role of convective organization and its implications for the scale-separation assumption at the root of convective parameterization schemes. However, cloud-system resolving models will not make convective parameterization redundant, but move the problem downscale to the planetary boundary layer and demand improved microphysical parameterizations.

Ensemble vs Local Convection

Convective cloud models can be broadly categorized as follows. First, a quasi-statistical approach where clouds of different types and/or in various stages of evolution are simulated in large computational domains (i.e., cumulus ensemble models or cloud-system resolving models). In this article, the terms cloud model, cloud-system resolving model, and cumulus ensemble model will be used interchangeably.

A prime objective is to quantify how convection interacts with the large scales of motion. For example, large-scale advective ‘forcing,’ the primary source of convective available potential energy, is derived from an objective analysis of sounding networks and applied as domain-mean tendencies of temperature and moisture (continuously forced convection). This approach has been used extensively in the west Pacific warm pool region Tropical Ocean Global Atmosphere–Coupled Ocean Atmosphere Response Experiment (TOGA COARE) and the eastern Atlantic Global Atmospheric Research Program’s Atlantic Tropical Experiment (GATE).

Second, in the initial-value approach (e.g., the classical cloud model), convective evolution is simulated over periods of hours. The initiation (or triggering) of convection is important: cold pools, surface fluxes, or stochastic perturbation locally force new convection. Such simulations are useful in their own right, for model development, and for model validation when used in conjunction with field campaigns.

Mesoscale Organization of Moist Convection

The past decades have witnessed advances in the understanding of organized convection, with convection over the tropical oceans being a focus. Figure 2(a) and 2(b) shows the evolution of numerically simulated convective cloud systems in the west Pacific warm pool region and eastern Atlantic region, respectively. In the former, cloud systems travel in one direction and embedded convection in the opposite direction. Synoptic-scale easterly waves modulate convection in the eastern Atlantic because they strongly affect environmental shear and large-scale forcing, and thereby convective organization and intensity. Shallow convection evolves to nonsquall (slow-moving) deep precipitating cloud systems that travel westward, steered by the mean wind. Fast-moving squall systems subsequently develop as the lower-tropospheric shear intensifies. The simulated cloud systems become less organized and produce less surface precipitation as the forcing decreases.

The simulated domain-averaged surface rainfall (mm) and stratiform amount (percentage) for both the west Pacific warm pool and the east Atlantic regions are shown in Table 2. The ratios between evaporation and condensation, sublimation and deposition, and deposition and condensation illustrate the relative importance of liquid vs ice processes and source and sink terms associated with water vapor. The microphysical processes are decomposed according to the regime of convective organization: slow-moving, fast-moving, less organized convective episodes in the east Atlantic, vigorous deep convection to gather with weaker convective events in the western Pacific during the convectively active phase of the intraseasonal oscillation where the stratiform component is larger. The dominance of warm rain processes in the east Atlantic region squall and nonsquall convective systems explains the smaller stratiform rain amounts. The depleted ice processes on 6 and 8 September are indicative of shallow convection. In contrast, ice processes are important for both active and relatively inactive convective periods over the west Pacific.

Figure 3 shows numerically simulated three-dimensional cloud systems over the west Pacific warm pool. Organized mesoscale convective systems consist of families of leading edge, quasi-linear, heavily precipitating cumulonimbus followed by an extensive area of trailing light (stratiform) precipitation. The cumulonimbus slope with height is due to the environmental wind shear. Mesoscale descent behind the leading edge develops mainly at low levels where evaporative cooling is strongest. Ascent occurs above the mesoscale ascent, typically separated by the 0 °C (melting) level. Evaporative-cooled downdraft outflows (density currents) provide localized uplift that triggers convection. Convectively generated gravity waves occur in the upper troposphere.

Cloud-system resolving models with large computational domains quantify how convection organized on mesoscales

Figure 2 Time sequence of the two-dimensional cloud model estimated domain mean surface rainfall rate (10^{-3} m h^{-1}) for (a) the west Pacific warm pool region and (b) the east Atlantic region. Adapted from Tao, W.-K., 2003. Goddard Cumulus Ensemble (GCE) model: application for understanding precipitation processes. AMS Meteorol. Monogr. Cloud Syst. Hurricanes TRMM, 107–138.

interacts with large-scale tropical waves and intraseasonal oscillations. For example, Figure 4 is a realization of Madden-Julian-like tropical intraseasonal variability. Figure 4(a) shows an eastward-traveling convective envelope while Figure 4(b)–4(d) shows the westward-traveling organized convective systems embedded in the envelope and steered by the mean flow. The fact that multiscale convective

organization occurs even with a uniform sea surface temperature (SST) indicates that it is a self-organizing process.

The above modeling studies have quantified many observed properties of moist convection and its multiscale organization. The challenge now is to understand how this organization relates to the large-scale atmospheric circulation.

Table 2 Cloud model-simulated domain-average surface rainfall (mm), stratiform amount (percentage), and microphysical processes (ratios between evaporation and condensation, sublimation and deposition, and deposition and condensation) for (a) the west Pacific warm pool region and (b) the east Atlantic region. For west Pacific warm pool region, the cloud model results are also separated into subperiods, deep strong convection during 20–23 and 24–25 December and weaker convection prior to, between, and after the deep convection (19–20, 23–24, and 25–26 December 1992). Slow-moving (nonsquall, 2–4 September), fast-moving (squall, 4–6 September), and less-organized (6–8 September) periods for the cloud model-simulated east Atlantic region results are also shown

(a) West Pacific warm pool region (19–26 December 1992)			
	After WWB (2 days)	Pre and during WWB (4 days)	
Total surface rainfall (mm)	50.8	85.1	
Stratiform amount (%)	42.0	48.0	
Evaporation/condensation (%)	62.0	73.0	
Sublimation/deposition (%)	46.0	50.0	
Deposition/condensation (%)	34.0	41.0	

(b) East Atlantic region (2–8 September 1974)			
	Slow-moving	Fast-moving	Random
Total surface rainfall (mm)	43.34	39.62	8.50
Stratiform amount (%)	27.0	26.0	44.0
Evaporation/condensation (%)	58.0	44.0	68.0
Sublimation/deposition (%)	36.0	27.0	24.0
Deposition/condensation (%)	23.0	25.0	9.5

Heat and Moisture Budgets

The collective effects of subgrid convection are represented by parameterizations. The budgets of heat, moisture, convective mass flux, and convective momentum transport can be derived from observations. Heat and moisture transports by convection strongly affect large-scale atmospheric dynamics. Transports are estimated from the objective analysis of sounding networks as thermodynamic budget residuals the apparent sources of heat (Q_1) and moisture (Q_2). Figure 5(a) shows that convective heating has a maximum in the 600–650 hPa layer. In the stratiform region (Figure 5(b)), heating is maximum in the upper troposphere (around 400 hPa), with cooling prevailing below the melting level. The stratiform heating is smoother because convective bursts have a more rapid evolution than the mesoscale processes in the stratiform region. Also, stronger heating occurs aloft, and stronger cooling below in the stratiform region owing to the evaporation of rain produced by melting ice particles.

Figure 5(c) and 5(d) shows the apparent moisture sink Q_2 . Drying in the convective region is caused by the condensation processes associated with cloud updrafts, and its maximum is lower than the apparent heat source. In the stratiform region, there is strong moistening (by evaporative cooling) below the 600-hPa level with weak drying aloft. Cloud models show that the eddy transport of heat is one order smaller than the effects of the microphysical processes, contrasting with the eddy transport of moisture, which is of the same order. These

Figure 3 (a) Horizontal and (b) vertical cross-sections of vertical velocity (filled contours) and total cloud mixing ratio (solid contour) taken from a three-dimensional cloud model simulation of the west Pacific warm pool region precipitating system (during a Westerly Wind Burst episode). The location of the vertical cross-section shown by the vertical line in (a).

distinctive heating/moistening patterns are consistent with observed mesoscale convective systems. The small difference (balance) between the cloud processes (response/feedback) and large-scale forcing is indicative of the quasi-equilibrium state of the tropical atmosphere.

Convective Mass Flux

Convective mass flux is an important quantity in the parameterization of convection in large-scale models but difficult to observe accurately; therefore, cloud models are essential. Figure 6 shows the 7-day evolution of simulated cloud mass fluxes (total condensate exceeding 0.1 g kg^{-1}). The larger mass fluxes trace the organized cloud systems (nonsquall clusters, days 2 and 5; and squall line, day 4). Evaporative cooling associated with the downdrafts is about half of the condensational heating in the updrafts (Table 2). Convective updrafts account for approximately 75% of the cloud updraft mass flux, yet occupy a mere 12–14% of the total area; these so-called ‘hot towers’ play a critical role in the heat and moisture budgets in the tropics, despite the small fractional area they occupy. Downdrafts account for about 30% of the mass flux, suggesting they are active over relatively small areas.

Figure 4 Clockwise from left: (a) Space-time distribution of surface precipitation simulated by a 40-day, two-dimensional 20 000 km domain cloud-system resolving model of tropical convection for a constant sea-surface temperature aquaplanet. Dotted green line indicates the eastward-propagating large-scale convective envelope, and full green line westward-propagating mesoscale convective systems; (b) shows the total condensate and precipitation distribution in a typical mesoscale system; and (c) shows the horizontal component of the system-relative airflow, and the flow organization. Workshop on New Insights and Approaches to Convective Parameterization, Reading, ECMWF, UK, 128–156.

Convective Momentum Transport

The vertical transport of momentum by convection affects the conversion of kinetic energy from subgrid-scale eddies to the mean flow, the rate of frictional dissipation, and the atmospheric energy spectrum. However, the large-scale effects of momentum transport represented by convective parameterizations are not always applied in large-scale models. The horizontal pressure gradient force within cloud systems affects convective momentum transport, but is difficult to measure accurately from observations mainly because the pressure field is a strong function of convective dynamics. Theoretical models show that convective momentum transport in mesoscales can be either upgradient, which enhances the mean flow, or downgradient in which case it is a mixing process. The existence of these (opposing) effects is supported by observations. Entropy considerations would suggest that, on average, momentum transport must be downgradient, with upgradient transport occurring in special conditions (e.g., in highly organized squall systems). The largest upgradient momentum fluxes occur in organized flow. Cloud models are instrumental for quantifying convective momentum transport and in deriving physically based parameterizations.

Convectively generated gravity waves affect the momentum balance of the atmosphere, and are particularly important in the tropical stratosphere and mesosphere. The wave generation mechanism and its vertical propagation to the deep atmosphere are being studied using cloud models.

Diurnal Variability of Precipitation

Cloud models have quantified the mechanisms responsible for the diurnal cycle of precipitation processes over the tropical oceans associated with the diurnal variation of radiation. The diurnal variation of rainfall can be simulated even when the diurnal variation of SST is suppressed. However, the maximum rainfall is shifted from nighttime (0200 Local Solar Time) to early morning (about 0500 LST) with suppressed diurnal variation of SST. While the diurnal variation of SST modulates rainfall processes, it may play a secondary role in the diurnal variability. Cloud models also indicate that convection is modulated by the diurnal change in available water as a function of temperature and is responsible for the nighttime maximum in rainfall. This implies that the increase (decrease) in surface precipitation associated with long-wave cooling (solar heating) may be due to an increase (decrease) in relative humidity. However, the interaction of radiation with organized convection can affect the diurnal variability of rainfall. Well (less)-organized cloud systems can produce strong (weak) diurnal variations in rainfall, but ice processes enhance the diurnal variation of precipitation.

Prediction of the diurnal cycle of convective precipitation has low skill over land, for reasons not well understood. The development of the diurnal evolution of the convective boundary layer, the role of orography and propagating convective systems, and the effects of land surface processes are all involved. Concerning the diurnal cycle of precipitation over tropical islands, sea breezes and land breezes and their interaction with coastlines and orography are key mechanisms. Cloud models have addressed these aspects in considerable detail.

Water and Energy Cycles

Cloud models are used in studies of the tropical water and energy cycles. In this context, the models typically run for several weeks until the temperature and water vapor fields reach a quasi-equilibrium state. They can produce different quasi-equilibrium states (warm and humid vs cold and dry), even though similar initial thermodynamic profiles and fixed SST are used. Stronger surface winds tend to produce a warmer and more humid thermodynamic equilibrium state. The moist static energy budget further indicates that the large-scale forcing of water vapor is another process responsible for warmer and more humid equilibrium states.

Cloud models have also been used to quantify hypotheses relating to global warming. Key results to date are (1) conversion of ice-phase water into the vapor phase associated with the dissipation of upper-level stratiform/cirrus clouds contributes to upper tropospheric moisture on the same order as moisture transport from deep convection; (2) cloud activity is much more sensitive to convergence in the large-scale atmospheric circulation over an oceanic warm pool than it is to the local SST; and (3) organization of cloud systems modulate the magnitude of upper-level cloudiness and moisture profiles. The above conclusions do not say whether or not global warming is occurring, only that if cloud processes are neglected or poorly

formulated, the consequences could lead to substantial errors in climate hypotheses.

Conclusion

Observations together with cloud models are a promising approach for improving and testing representations of cloud processes in numerical weather prediction models and climate models. Observations provide both the initial conditions and model-validation data. Modern cloud models operate with reasonable, albeit incomplete, microphysical parameterizations and simulate the evolution, structure, and life cycles of cloud systems. They also explicitly calculate interactions between clouds and long-wave and solar radiation that are difficult, if not impossible, to measure observationally.

During the past five decades, cloud models have advanced from simple process models to full multiscale cloud-system simulators that span a dynamic range of 1 km to planetary scale. They are helping improve our understanding of the interaction between convection, radiation, and the large-scale environment. They address basic issues in global and regional prediction, as well as fundamental problems associated with the Earth's water and energy cycles. They are used extensively to improve physical parameterizations. Because of the dynamic range of modern cloud-system models, space-based remote sensing is an ever more necessary part of model validation.

Synopsis

Contrails are anthropogenically induced clouds that have the potential to impact climate and reveal aircraft positions. Contrail formation is governed by temperature and humidity fields and is generally limited to temperatures below -40°C . Contrail growth and transformation into cirrus clouds is more complex and must be understood to fully account for contrail effects on climate. Contrail microphysical and optical properties as well as coverage, location, and illumination conditions are also critical for determining contrail radiative forcing, a climate change metric. *In situ* measurements, satellite remote sensing, cloud process models, and climate models are used to study contrails and their potential impacts on global climate.

Introduction

One of the most visible anthropogenic effects on the atmosphere is the condensation trail or contrail. These aircraft-induced clouds have become a common sight since the 1960s because of increasing jet traffic, but were observed as early as 1919. Contrails were frequently seen and filmed during World War II during bombing raids or dogfights. They were briefly studied in Germany during the war but drew little scientific interest again until the early 1950s when the use of jet aircraft by military and commercial aviation accelerated. Interest waned with only sporadic studies until the 1990s when aircraft exhaust and contrails became the foci of numerous research efforts. Concerns over their impact on climate and aircraft visibility have been the primary motivation for the recently intensified research into contrails. Climate researchers are interested in knowing whether they cause warming or cooling of the atmosphere, while military mission planners would prefer that contrails do not reveal the positions or paths of their aircraft. Understanding the contrail effects requires knowledge of their physical and optical characteristics and how, when, and where they form.

Contrail Formation

Contrails are generally composed of ice crystals with trace amounts of exhaust products such as soot and sulfates. The contrail ice crystals form because the relative humidity with respect to liquid water U_w temporarily reaches the saturation point in the plume mixture of ambient air and hot exhaust gases. Tiny droplets develop on background aerosols or on aerosols formed by exhaust compounds. Because the ambient temperatures required for contrails are generally colder than -40°C , the small water droplets instantly freeze and grow via vapor-to-ice deposition as long as the relative humidity with respect to ice U_i remains above 100%. They dissipate via sublimation if U_i is below the saturation point or by precipitation into unsaturated layers below the flight level.

Aerodynamic Contrails

Another type of contrail that forms at higher temperatures is the aerodynamic contrail that forms behind the tips or the

leading edges of aircraft wings. These are commonly seen emanating from subsonic aircraft in humid atmospheres, usually at low levels. In these cases, the ambient air is compressed at the wing tip and then expands quickly during adiabatic expansion within the low-pressure area above the wing tip. The expansion temporarily cools the air sufficiently so that it falls below the dew point resulting in condensation. Aerodynamic contrails are most commonly seen at low altitudes where they form short-lived liquid water contrails. Sometimes, at temperatures slightly greater than -40°C , they can form ice crystal trails that will persist if the air is supersaturated with respect to ice. Modeling studies indicate that they are likely to be important in tropical latitudes where cruising altitudes are more often at temperatures slightly greater than -40°C . Because ice contrails generated from aircraft exhaust are the more common variety, aerodynamic contrails are not considered any further here.

Exhaust Contrails

The basic concepts for determining the conditions for contrail formation were independently developed by E Schmidt in Germany during 1941 and H Appleman in the USA during 1954. The lines in Figure 1 schematically illustrate the ice contrail formation process for several scenarios with the ambient temperatures T_a and water vapor partial pressures e_a indicated by the points at the lower end of each line. Each line

Figure 1 Phase diagram with mixing lines for aircraft exhaust in different ambient conditions.

extends to the temperature T_e and water vapor partial pressure e_e of the exhaust exiting the engine. As the exhaust gases mix with the ambient air, the mean temperature and moisture properties of the mixture follow these mixing lines until they approach the ambient conditions. In cases defined by the lines I, II, and IV, the ambient water vapor pressure is less than the ice saturation partial pressure e_i , while in Case III, $e_a > e_i$. In Case I, the partial pressure exceeds e_i during the mixing but never reaches water saturation and a contrail does not develop. A short-lived contrail would develop in Case II because at point F, the mixture temperature T_F coincides with the liquid water saturation partial pressure e_w . The contrail would form when the plume temperature reached T_F and persists until the plume partial pressure decreased to a value below e_i at approximately -42°C . A long-lived, persistent contrail would form in Case III, because the ambient air is supersaturated with respect to ice. Because saturation conditions cover a greater range of temperatures after initial formation, the contrail formed in Case IV would probably last longer than that in Case II.

Although contrail formation has been observed at temperatures as great as -36°C , it is clear from Figure 1 that contrails form more easily at lower temperatures. The threshold temperature T_T for contrail formation is defined as the warmest ambient temperature that will support contrail formation for a given value of e_a and the exhaust parameters T_e and e_e . The latter quantities determine the mixing line slope G and are a function of engine type, operating conditions, and fuel, while the value of e_a can be determined from vertical profiles of atmospheric and dew point temperatures. In Case II, the ambient temperature at point T is the contrail formation threshold temperature for the given values of e_a and the mixing line slope G . That is, the ambient temperature enabling contrail formation temperature would have to change if either e_a or G varied and, therefore, T_T is unique for each pair of e_a and G . The threshold temperatures are greater than T_a for Cases IV and III, and less than T_a for Case I. To find T_T for a particular slope and e_a , it is necessary to determine the tangent point T_F for a line having slope G with the curve describing the variation of e_w with T . Given a value of G , the threshold temperature can be computed for T_F between -10 and -60°C using

$$T_F = -46.46 + 9.43\ln(G - 0.053) + 0.720[\ln(G - 0.053)]^2 \quad [1]$$

where G is given in Pascals per Kelvin. The threshold temperature for any value of U_w or e_a can be determined iteratively with

$$T_T = T_F - [e_w(T_F) - U_w e_w(T_T)]/G \quad [2]$$

The mixing line slope depends on the specific plume enthalpy h_p and the water vapor mixing ratio q , which, in turn, are related to the emission index EI_w , mass specific combustion heat Q , and the overall engine efficiency η . Specifically,

$$G = \Delta e / \Delta T = [\Delta q / \Delta h_p] p c_p / \varepsilon = \text{EI}_w p c_p / [\varepsilon Q (1 - \eta)] \quad [3]$$

where c_p is the specific heat capacity, p is the pressure, and $\varepsilon = 0.622$. The emission index, the mass of water produced per mass of combusted fuel, accounts for Δq since $e_e \gg e_a$. The enthalpy differential is also determined almost entirely by Q and η because the ambient heat is negligible compared to that produced by the engine. Since Q and EI_w can be determined for a given fuel, then the overall efficiency, the ratio

Figure 2 Hypothetical mixing lines for different propulsion efficiencies.

of propulsion energy to total combustion energy, is the primary variable affecting the mixing line slope. The slope of the line increases with increasing efficiency. Each type of engine has a nominal efficiency that is based on stationary operating conditions. The overall efficiency, however, may vary for a given engine because of different airframes, maintenance, and operating conditions. Figure 2 illustrates the impact of efficiency for a given set of ambient conditions. In this instance η_2 is slightly less than η_1 resulting in a contrail from the airplane with η_1 and no contrail from the one with η_2 . Thus, two airplanes flying in the same environment can produce two different results. Similarly, an airplane might produce a contrail when it is cruising but not when it is ascending, depending on the effect of acceleration on the efficiency.

Contrails typically form at a distance of about 30 m or less behind the aircraft engines where the turbulent mixing has sufficiently reduced the temperature. The latest research results indicate that the initial condensation of the supercooled droplets takes place on a wide variety of particles including exhaust products, e.g., sulfate aerosols, soot, and metallic particles as well as ambient mineral aerosols. When the contrails are about 1 min old, the mean particle radius is around $2\ \mu\text{m}$ and increases up to $4\text{--}5\ \mu\text{m}$ after 3 min. A wide variety of particle shapes have been observed in young contrails including hexagonal columns and plates, triangles, irregular forms, and spheroids. Young contrails often appear saw-toothed or appear to have a cellular structure that results from the wake vortices formed by the aircraft. The wake vortex pairs act to extend the contrail vertically with irregularities that can lead to formation of local convective cells or radiative cooling gradients that aid mixing of the contrail with the ambient air.

Contrail Growth and Structure

Once formed, a contrail develops or dissipates in the same manner as a naturally generated cirrus cloud. Contrail growth and spreading depend on the thickness of the supersaturated layer, the degree of ice supersaturation, the nature of the wake vortex, and the wind velocity and shear. When contrails persist, the particles typically grow to lengths from 30 to $1000\ \mu\text{m}$, sizes usually associated with natural cirrus clouds. Ice particle growth is rapid in highly supersaturated layers and results in fall streaks that spread horizontally in lower layers according to

Figure 3 Schematic depiction of contrail spreading in conditions with and without wind shear.

the wind shear. **Figure 3(a)** shows a cross-sectional view of a hypothetical persistent contrail growing and spreading in the absence of vertical wind shear. When wind shear is present (**Figure 3(b)**), the contrail may spread mostly by turbulent mixing induced by the aircraft vortex or by radiative processes. It may also thicken by turbulence or through precipitation. If the crystals fall into supersaturated air below, they will continue to grow or, possibly, split into additional crystals. The linear shape of the contrail will be distorted and the contrail will soon look like a natural cirrus cloud to the observer.

An example of this shear effect is seen in **Figure 4**, which shows the cross-sectional growth of a contrail observed with a surface-based scanning lidar. After 1.1 min (**Figure 4(a)**), when the vortex effect is dissipating, the overall width of the contrail is only ~ 160 m compared to its vertical depth of roughly 260 m. It grows progressively wider during the following 14 min reaching a horizontal extent of 1 km (**Figure 4(d)**). As it widens, the lower part of the contrail starts evaporating (**Figure 4(b)**) in the dry layer below the 10.35-km level, while the upper portion slowly rises due to the buoyancy resulting from the release of latent heat into the air from the condensation-freezing process producing the ice particles. The wind mean vertical wind shear for this case was $\sim 4 \text{ m s}^{-1} \text{ km}^{-1}$.

Contrails that are older than several hours are often indistinguishable from natural cirrus clouds regardless of shear conditions. Most studies indicate that the number of crystals in a contrail remains essentially constant after formation in supersaturated conditions. Thus, if the contrail precipitates, the contrail cloud at flight level might gradually fade as its particles are depleted. If e_a is just above ice supersaturation, then the crystal growth will be limited and little precipitation occurs. In this case, the contrail may spread slowly by diffusion, maintaining its linear shape for a relatively long time. Because the crystals grow by deposition, the amount of ice water in the contrail increases until the particles fall out or equilibrium is reached between the ice water content and e_i . Such equilibrium conditions generally do not last very long and the contrail eventually dissipates. Although most persistent contrails observed from satellites have visible optical depths between 0.10 and 0.4, the values are highly variable ranging between 0.01 and 2. Optically thin contrails may occur frequently but

most cannot be detected in satellite imagery. The lifetimes of contrails are also extremely variable. Short-lived contrails may only last a few seconds while some contrail-generated cirrus

Figure 5 Schematic depiction of contrails forming in an on-off pattern: (a) due to wave action; (b) due to ascent through dry and moist layers.

clouds have been tracked for more than 17 h. The shape, size, optical properties, and life cycle of contrails are highly dependent on their environment, so that a multitude of contrail morphologies can occur. Contrail-cirrus clouds are generally similar to natural cirrus clouds within a few hours after their formation.

Because water vapor and temperature are not homogeneously distributed, even at relatively small scales (~ 100 m), contrails may form or persist in an apparently erratic fashion as shown in Figure 5. For example, an on-off pattern can occur as an aircraft flies through a moist layer disturbed by a vertical wave or even weak convective plumes. The contrails in Figure 5(a) form in the ascending parts of the wave or plume where the temperature of the rising air drops below the threshold temperature, while in the descending portions the air warms and dries resulting in no contrail formation. Similar patterns can result from an airplane ascending or descending through several thin layers that are near saturation but separated

by dry layers as in Figure 5(b). The persistence of a contrail or parts of it depends on the value of e_a relative to e_i along the contrail line. Thus, parts of a contrail may rapidly dissipate while other portions may linger and even grow. The local turbulence induced by the airframe, the atmospheric stability, and the wind vector also affect the morphology of the contrail.

Photographs of the most familiar type, short-lived contrails are shown in Figure 6. In both cases, the trails gradually fade without much spreading. In those situations, e_a is only slightly less than e_i . When e_a exceeds e_i , less familiar shapes can occur. In the top panel of Figure 6, the contrail dissipates several kilometers behind the aircraft. The lower panel shows several intermittent contrails (e.g., Figure 5) that persisted for less than an hour with little spreading. Figure 7 shows examples of contrails at different stages of growth or persistence at the same time in different parts of the sky as seen by an observer at Ft. Monroe, Virginia. East of the observer (Figure 7(a)), the contrails appear to maintain their linearity in the foreground

Figure 6 Short-lived contrails.

Figure 7 Persistent contrails in various stages of growth and decay as seen: (a) east; (b) south of Ft Monroe, VA at 16.25 UTC, 21 May 2010.

except for the curved contrail crossing many of the other contrails. Toward the horizon, it appears that the contrails have spread out and lost some of their linearity, looking more like natural cirrus. One contrail appears to be segmenting. To the south (**Figure 7(b)**), a succession of slowly spreading contrails extends off to the hazy horizon. Different parts of these contrails spread differently with the sections near the center of the photograph shifted and twisted slightly compared to the rest of the contrail segments. Many of these contrails persisted for at least several hours before advecting southeastward out of view.

Condensation trails often form ahead of advancing fronts in the poleward flow of an upper-level trough where conditions are not quite saturated enough for natural cirrus development. In these instances they can occur at multiple levels in the atmosphere because the formation conditions often cover a large depth of the atmosphere and air traffic uses a wide range of altitudes, but they also form in a variety of other conditions. In **Figure 7**, the contrails formed from moisture advecting westward from the high altitude outflow of an occluding low-

pressure system approximately 1400 km west of the observer. The atmosphere was saturated with respect to ice at temperatures below -40°C in many layers between 9.9 km (32.7 kft) and 13.1 km (43.2 kft). Thus, the formation of crossing contrails, which only occur because airplanes fly at different flight levels depending on flight path direction, is likely for this case because of the depth of the saturated layers.

The contrails seen in **Figure 7** are part of a larger area of contrails that is evident in infrared images (**Figure 8(a)**) from the MODerate-resolution Imaging Spectroradiometer (MODIS) on the Terra satellite. These images were taken around the same time as the photograph in **Figure 7**. Subsequent imagery shows that these contrails dissipated downstream to the east, while additional contrails formed within or beneath the advancing thin cirrus clouds.

Contrails can form within cirrus clouds where they are manifested by reduced particle sizes or local thickening of the cloud. Aircraft exhaust can also affect supercooled liquid water clouds that have temperatures below the threshold value. When an airplane flies through this type of cloud, the dynamic

Figure 8 Infrared temperature and temperature difference images of contrails over Maryland, Virginia, and North Carolina, USA from the Terra 1-km resolution MODIS at 16.15 UTC, 21 May 2010. Cross indicates position of observer in **Figure 7**.

pressure changes due to flow over the wing edges or behind propeller tips cause cooling sufficient to freeze the surrounding cloud droplets. The thermodynamic equilibrium shifts from a vapor-to-liquid to vapor-to-ice process causing a rapid depletion of the available water vapor onto the frozen droplets. Newly formed ice crystals quickly grow large enough to fall out of the cloud resulting in a streak below the cloud and a gap within in the cloud.

This gap, called a distrail, hole punch cloud, or canal cloud, is linear when the airplane flies for an extended distance within the cloud or oval shaped when the aircraft is briefly inside the cloud as it ascends or descends. Depending on the conditions, especially the original cloud thickness, a distrail will either persist or be filled in with a new water droplet cloud. In very moist conditions, significant snowfall can occur along the path of the aircraft. Distrails are most frequently observed in altostratus or altocumulus clouds.

Contrail Remote Sensing

Although contrails are most often identified by their linear shapes both from ground observations (Figure 7) and satellite imagery (Figure 8), these man-made clouds can take on other geometric shapes according to the particular flight patterns and winds. For instance, spiral shapes result from an airplane in a circular holding pattern within an advecting supersaturated layer, while a figure eight can form in a similar type of layer if the airplane flies in a linear holding pattern. The linear structure is most common and forms the basis for automated identification of contrails. Because detection of contrails is important for various scientific applications, methods have been developed for differentiating contrails from other linear clouds in satellite imagery, the only plausible data source for studying the spatial and temporal distribution of contrails and their physical characteristics. Automated techniques for contrail detection typically create an image of a parameter most likely to be associated with a contrail, then apply a variety of image processing methods to find linear structures within that image.

Such methods, which are still being researched, usually take advantage of the relatively distinct infrared optical properties of younger contrails to compute a parameter that is likely to yield a distinctive contrail signal for image processing. Because of their relatively small size (mean effective radii between 5 and 25 μm), the ice crystals in contrails have single-scattering albedos that increase more with decreasing wavelength λ in the thermal infrared region (3.5–15 μm) than the single scattering albedos of larger particles typically found in most cirrus clouds (effective radii greater than 15 μm). Thus, contrails usually transmit more radiation at shorter infrared wavelengths than a cirrus cloud of equivalent optical depth, resulting in a signal that often reveals a contrail.

To better understand this effect, consider that the satellite measures a spectral radiance L_λ that is recorded as a brightness temperature T_λ , which is proportional to λ through the Planck function. For a cloud or contrail, the observed radiance can be modeled simply as:

$$L_\lambda = \varepsilon_\lambda L_c + (1 - \varepsilon_\lambda) L_b \quad [4]$$

where L_c is the radiance emitted at the cloud temperature T_c , L_b is the upwelling radiance at the cloud base with an equivalent brightness temperature T_b , and ε_λ is the cloud emissivity. In general, $L_b > L_c$, so that an increase in cloud transmissivity ($1 - \varepsilon_\lambda$) results in more transmission of L_b and a larger value of L_λ . Thus, T_λ will be greater at shorter wavelengths than at longer ones as long as the cloud is optically thin (ε less than 0.9 or so). This effect can be seen in Figure 8, which shows the 11- μm temperature (T11) image and an image of brightness temperature difference (T11 – T12) between the 11- and 12- μm channels of the Terra MODIS. Some of the contrails are readily apparent in the 11- μm image (Figure 8(a)) but are obscured by other cirrus clouds. The temperature difference image in Figure 8(b) reveals many contrails that were not evident in the standard infrared image and highlights others more clearly. Even the curved contrail in Figure 7(a) can be seen crossing over some of the parallel contrails east of the observer's location in Figure 8(b). Because the actual temperature difference contrast depends on the effective particle sizes and optical depths of the surrounding clouds, and those quantities are naturally variable, the contrails are not always detected. Furthermore, other features such as cirrus streaks, coastlines, or cloud edges may produce similar signals.

When T_b is not very different from T_c , such techniques do not reveal the contrails very readily because the signal is so small. Therefore, contrails imbedded in relatively thick cirrus clouds cannot be seen in most temperature difference imagery. However, during the daytime, contrails can often be detected using temperature differences between a channel near 11 μm and one in the shortwave (SW) infrared wavelength range (3.5–4.5 μm). At the shorter wavelengths, the satellite imagers measure an emission component and a solar reflected component. The smaller contrail ice crystals reflect more sunlight than the surrounding cirrus crystals resulting in a relatively large brightness temperature. Figure 9 shows MODIS imagery for the same case as in Figure 8, except that it is shifted westward covering parts of Ohio, Pennsylvania, Virginia, and West Virginia. The 11- μm image in Figure 9(a) shows little sign of contrails, particularly in the thick cirrus over Ohio, Pennsylvania, and West Virginia, while the T11 – T12 image (Figure 9(b)) reveals a few contrails over those same areas. The 11- and 3.7- μm temperature difference (T3.7 – T11) image (Figure 9(c)), however, reveals a large number of linear contrails around the common borders of those states. These contrails are absent or faint in Figure 9(b). Conversely, where thick cirrus is absent (e.g., South Central Virginia), the contrails are more prominent in Figure 9(b) than in Figure 9(c). Thus, the two images tend to complement each other with respect to contrail detection. Further enhancement of the photograph would likely reveal more contrails in the temperature difference images. Again, the ability to detect contrails in a thick cirrus cloud depends on many factors including the contrail age and its relative depth in the cloud as well as the particle sizes in the cirrus cloud, and the viewing and illumination conditions. To date, the T3.7 – T11 information has not been employed to monitor contrails for climate purposes since it is applicable only during the daytime, and contrails imbedded in thick cirrus clouds will likely have minimal radiative impact.

Contrails can also be detected in high-resolution visible and near-infrared imagery in certain conditions. For example, when

Figure 9 Contrails imbedded in thick cirrus over Ohio, Pennsylvania, Virginia, and West Virginia from the Terra 1-km resolution MODIS at 16.15 UTC, 21 May 2010. (a) 11- μm brightness temperature; (b) 11–12 μm brightness temperature difference; (c) 3.7–11 μm brightness temperature difference images.

not imbedded in cirrus or over lower clouds, a young contrail is often reflective enough to be seen as a bright line in a 1-km visible channel image. Sometimes, the contrail will cast a shadow on lower clouds and can be detected from its shadow. Near-infrared channels on or near water vapor absorption lines, like that near 1.38 μm , often do not receive any significant reflectance from lower clouds so that even very thin high clouds, such as contrails, can be detected.

Figure 10 shows an example of a contrail outbreak over Florida at 16.00 coordinated universal time (UTC), 23 March 2011 as seen in Terra MODIS. Very faint contrails can be seen west of the peninsula in the true color image (Figure 10(a)) with little indication of contrails near the Georgia–Florida border. The 1.38- μm reflectance image (Figure 10(b)) reveals a mass of crossing contrails along the border and fine detail of the contrails and contrail–cirrus over the whole area. The spread of the contrails and cirrus clouds is greater in Figure 10(b) than in the true color image (Figure 10(a)) or the T11 – T12 image (Figure 10(c)). When there are no underlying clouds, the 1.38- μm channel can reveal contrails with very small optical depths, which modeling studies suggest are quite common but are not seen in infrared imagery. Although potentially promising for more accurate monitoring of contrails, the 1.38 μm channel and other near-infrared channels are only applicable during the daytime and are strongly affected by underlying clouds. Thus, thermal infrared channels are mainly used for monitoring contrails.

Contrail properties such as temperature, height, optical depth, and effective particle size can be determined with the same methods used to remotely sense cloud properties from satellite imager data. Such techniques typically require multispectral imagers that can be used to simultaneously solve for ϵ , T_c , and the particle size. When an insufficient multispectral radiance set is available, one or more of the parameters must be assumed to obtain a solution for the other parameters. These methods generally provide results consistent with *in situ* measurements. Satellite analyses have found mean optical depths that average approximately 0.11 over Europe and 0.25 for the USA. Modeling studies show similar discrepancies

between contrails over the USA and Europe, but some have also indicated that the satellite retrievals miss large numbers of contrails having optical depths smaller than 0.05. The average temperature of contrails detected from satellite data over the midlatitudes is -54°C , which corresponds to an average pressure of about 200 hPa.

Contrail–Cirrus

An increase in cirrus cloudiness because of contrail formation has been hypothesized since the beginning of the commercial jet age. The possibility for enhanced cirrus coverage resides in the frequency and extent of areas that are ice supersaturated. *In situ* measurements and numerical model analyses have shown that e_a exceeds e_i 10–20% of the time in air at flight altitudes (8–12 km). Thus, the potential exists for substantial increases in cirrus coverage over areas crossed by air traffic. Because the stratosphere is generally very dry, aircraft flying above the tropopause generate few contrails, especially persistent ones.

The conditions necessary for supporting contrail formation at flight altitudes change with the seasons. Over midlatitude areas, contrail conditions are favorable most often during winter and early spring when the troposphere is coldest. During summer, the temperatures at flight levels are often too high to enable contrail initiation. Over areas poleward of about 50° latitude, the tropopause is often below flight level during winter, so that a significant number of airplanes fly in the stratosphere resulting in contrail suppression. Conditions are more favorable for contrails during the summer and autumn in the subarctic regions. In the tropics, the altitude for contrails is generally above 11 km year-round, so the potential for contrail formation is reduced for many commercial airplanes. However, persistent contrails are likely to occur more frequently in the tropics than at other latitudes at altitudes above 11 km because of more abundant water vapor.

Surface observations over the USA during the 1990s indicate that persistent contrails occur, on average, approximately 9% of the time, but the frequency varies from less than 5% in

Figure 10 Terra MODIS 1-km imagery taken 16.00 UTC, 23 March 2011. (a) True color; (b) 1.38- μm reflectance; (c) T11 – T12.

low traffic areas to 25% in the main air corridors. Approximately 80% of these persistent contrails are either imbedded in, extending from, or near natural cirrus clouds. Contrail coverage has been derived from satellite imagery only for those contrails that are linear and large enough to detect in 1-km infrared data. Satellite-based estimates of daily mean contrail amounts over central and western Europe, the North Atlantic, the conterminous USA, Japan, and Thailand are approximately 0.5, 1.0, 0.5, 0.3, and 0.1%, respectively, and, for the early 1990s, roughly 0.1% globally. Similar as well as much smaller or larger values have been derived from theoretical calculations using realistic air traffic patterns, numerical analyses of meteorological fields, and specified engine efficiencies. However, uncertainties in detecting contrails unambiguously with automated satellite image analysis techniques are still quite large.

Automated detection and assessment of contrail coverage have been confined to contrails that are identifiable by their linear structure and small particle sizes. Because these identifying features are often lost as the contrails spread, the linear contrail coverage estimates represent the minimum amount of the sky that is covered by contrails. The T11 – T12 images (Figure 11) from the AVHRR on the NOAA-16 and NOAA-19 satellites illustrate the difficulty of distinguishing contrails from cirrus clouds. The large area of cirrus clouds seen east of North Florida in Figure 10(b) began as hundreds of linear contrails north of the Florida peninsula at least 3 h earlier (Figure 11(a)). Those west of Florida were already quite wide at 12.56 UTC and extended as far west as Louisiana. The latter group dissipated by 17.35 UTC (not shown), while the former mass of contrails persisted as a collection of nearly contiguous

Figure 11 AVHRR T11 – T12 images for 23 March 2011 from (a) NOAA-16; (b) NOAA-19.

cirrus clouds over the Atlantic with a few scattered linear features (**Figure 11(b)**). Without following the linear contrails seen in **Figure 11(a)**, it would be impossible to differentiate the contrail–cirrus over the Atlantic in **Figures 10(b) and 11(b)** as separate from naturally forming cirrus clouds.

Geostationary satellite data can be used to track some contrails as they grow and change in shape and composition. Examination of the geostationary data (not shown) taken during 23 March 2011 revealed that the large contrail mass over the Atlantic actually started forming as early as 11.45 UTC over North Georgia and South Carolina and did not completely dissipate until 23.45 UTC. The long contrails west of Florida started forming over Louisiana around 08.00 UTC and lasted roughly 12 h. Published studies based on geostationary data indicate that the actual cirrus coverage generated by persistent contrails might be as large as a factor of 10 times the coverage estimated for younger, linear contrails. Other studies based on trends in cirrus cloud cover suggest that the coverage including the linear contrails is most likely to be between 1 and 4. Determination of contrail coverage and evaluation of the resulting changes in cirrus cloud amounts are topics of ongoing research.

Another approach to estimating the total change in cloud cover due to contrails is through modeling, which has been undertaken at various levels of complexity and detail. Typically, a model will use flight track distances within an atmospheric specified volume or other measures of air traffic and simulate

the production of contrails either by explicitly forming contrails and spreading them using a parameterization that differentiates them from natural cirrus or by adding cirrus to the atmosphere in proportion to the flight densities. Observations are often used to guide and/or validate these approaches.

Figure 12 shows an example of contrail and contrail–cirrus coverage estimated using a fairly sophisticated model. In this case, the coverage is broken down according to the derived contrail optical depth and age. Contrail–cirrus coverage is greatest over the Northern Hemisphere, especially over the North Atlantic, Europe, and the USA (**Figure 12(a)**), regions with considerable air traffic. Europe is downwind of the Atlantic corridor and receives contrail–cirrus advected from that area. The heavier traffic over the USA and Europe leads to significant coverage by young contrails (<5-h old), as seen in **Figure 12(b)**. The model indicates that most of the contrail–cirrus coverage is due to very thin cirrus having optical depths < 0.02 (**Figure 12(c)**). These very thin contrail–cirrus clouds would be difficult to detect visually from the surface or with passive imagery. Younger contrails comprise a larger proportion of the contrail–cirrus coverage in the Southern Hemisphere than over the north where some areas (e.g., Russia, Northern Canada) have negligible coverage due to young contrails (**Figure 12(d)**). Not shown are the areas where significant decreases in natural cirrus occurred in the model as a result of moisture being locked up in contrail cirrus. For example, the largest drops in natural cirrus coverage occurred

Figure 12 Average 2002 contrail-cirrus and young contrail coverage as simulated by ECHAM4-CCMod. Coverage due to (a) contrail cirrus; (b) persistent young contrails up to 5-h old; (c) visible contrail-cirrus with optical depth > 0.02 ; (d) fraction of contrail-cirrus due to contrails up to 5-h old. Coverages are computed assuming maximum overlap among contrails or contrail-cirrus coverage leads to increased overall cloud coverage. Reproduced from Burkhardt, U., Kärcher, B., 2011. Global radiative forcing from contrail cirrus. *Nature Climate Change* 1: 54–58.

over the Eastern USA, Europe, and the northwest coast of Africa. Although the results discussed here have not been validated to date, they reveal the complexity of the problems faced in quantifying contrail impacts on cloudiness. Other models have produced different results and more research is needed to determine how accurately each model represents the actual atmospheric conditions.

Contrail Climate Effects

Contrails, like other cirrus clouds, can affect both the hydrological and radiation budgets. Many of the possible contrail effects have only been the subjects of educated speculation, although some have been estimated to some degree. Some of these potential effects are mentioned here.

As noted earlier, by freezing out water vapor prior to the natural formation of cirrus clouds, contrails can alter the overall distribution of cirrus. Contrail formation may decrease precipitation in some clouds by reducing the average particle size in the affected clouds. Conversely, the precipitation induced by persistent contrails in otherwise clear air (e.g., [Figure 3\(a\)](#)) may result in moistening of the middle layers of the troposphere and drying of the atmosphere at flight altitudes.

As a thin cirrus cloud, contrails reflect some solar or SW radiation that would otherwise warm the surface and absorb outgoing infrared radiation that cools the surface-atmosphere system. The overall radiative impact depends on the contrast between the contrail and its background, the lifetime of the contrail, and the solar zenith angle when it is present. Depending on the solar zenith angle and the thermal and albedo contrasts between the contrail and background, either surface or lower clouds, the net forcing can result in cooling or warming of the system. For instance, if the contrail forms over a dark background during midday, the amount of reflected sunlight may exceed the amount of infrared radiation blocked and reradiated by the cloud. Conversely, if it develops over a bright hot surface (i.e., desert) during the day, a contrail may reflect little additional solar radiation, but trap a significant amount of infrared because it is so much colder than the surface. Its overall impact would be substantially different from that over the dark surface. A similar effect would occur for a contrail over a warm low cloud deck. At night, contrails warm the atmosphere. However, even during the day when solar and infrared forcings can almost cancel each other, the contrail will still impact the radiation field because most of the blocked sunlight results in cooling of the surface, while much of the infrared or longwave (LW) radiation ‘trapped’ by the contrail warms the upper troposphere and has little immediate impact on the surface. Currently, 60% of air traffic is estimated to occur during the daytime.

These radiative forcing (RF) effects have been estimated with several different models and assumptions resulting in a minor amount of global warming when averaged over a long time period or some slight cooling on an instantaneous basis. [Figure 13](#), which presents results from a general circulation model study, shows the distributions of linear contrail RFs assuming random contrail cloud overlap, an average contrail particle effective diameter of $30 \mu\text{m}$, and an optical depth of 0.2. This estimate is based on air traffic for 2002. The mean RFs for contrails in otherwise clear skies are shown on the left half of the figure, while on the right are those for all skies, including both cloud-free backgrounds and clouds computed within the model. Positive RF indicates warming and conversely, negative forcing denotes a cooling effect. The greatest LW RF for clear skies occurs over the Eastern USA ([Figure 13\(a\)](#)) where it exceeds 100 mW m^{-2} . [Figure 13\(b\)](#) shows that the LW RF is reduced by roughly a factor of 2 when clouds are included in

Figure 13 RF (mW m^{-2}) at the top of the atmosphere for 2002 air traffic. (a, b) LW; (c, d) SW; (e, f) net for (left) clear-sky forcings and (right) for all-sky forcings. Reproduced from Rap, A., Forster, P.M., Jones, A., et al. 2010. Parameterization of contrails in the UK Met Office Climate Model. *Journal of Geophysical Research* 115: D10205, doi:10.1029/2009JD012443.

the calculations. The SW RF is negative everywhere and strongest for cloud-free skies (Figure 13(c)) over the Eastern USA and Europe where it exceeds 500 mW m^{-2} . Inclusion of the clouds reduces the global SW RF by 60% to -3.8 mW m^{-2} (Figure 13(d)). Combining the SW and LW forcings yields a net RF of 12.9 mW m^{-2} for clear skies (Figure 13(e)) and 7.7 mW m^{-2} for the all-sky case (Figure 13(f)). While the net RF is positive over most regions, negative net RF is seen over a few areas in the Arctic, central tropical Pacific, and over Northeastern Asia.

This example is one of the many computed in various ways during the last two decades. Various scenarios by other researchers have yielded net RF values between 0.4 and 20.0 mWm^{-2} or more depending on many factors and the ways the model treats contrails and clouds. For example, use of a different approach to account for clouds in the model calculations performed for Figure 13 yields 12.0 mW m^{-2} . The

best estimate of global net RF from linear contrails as of 2009 for the year 2005 is 11 mW m^{-2} with a 90% confidence interval range from 5 to 25 mW m^{-2} . Yet, the scientists producing such estimates recognize that the level of scientific understanding remains low for such estimates. Even less understanding and confidence accompanies estimates of contrail-cirrus RF, which ranges from 11 to 87 mW m^{-2} . To put these results in perspective, the linear contrail RF constitutes roughly 20% of all aviation RFs excluding that from contrail cirrus, including those from ozone carbon dioxide, water vapor, and nitrogen compounds. The 2005 best estimate of RF for all aviation, however, is only about 4% of all estimated anthropogenic RF if contrail-cirrus is not included and could be 5% if it were included.

Since air traffic is expected to increase steadily in the coming decades, the same models used to estimate contrail RF for past or present air traffic have been employed to compute

the contrail RF for the future. Based on several scenarios of technology and air traffic changes, climate model estimates of mean linear contrail net RF range from 37 to 55 mW m⁻² for the year 2050. Inclusion of contrail–cirrus boosts the contrail/contrail–cirrus RF estimates up to as high as 315 mW m⁻². Current uncertainties in contrail coverage, optical depth, lifetimes, overlap with lower clouds, and other factors preclude a definitive assessment of the overall contrail impact. Despite these uncertainties, it is clear that, whatever effect they currently have on climate, it will increase in the future.

The Future

Contrails are difficult to study because of their high altitude, large advection rates, and frequent co-occurrence with natural cirrus. Thus, current estimates of their impact are highly uncertain. Nevertheless, their potential for affecting the global climate and providing military intelligence has spurred more interest and focused research into their formation, dissipation, microphysical and morphological characteristics, and methods for suppressing them. Removal of fuel sulfur or use of liquid hydrogen fuels has been suggested as means for diminishing the number of cloud nuclei and, hence, the number of contrails. Tests and theoretical studies have shown that such measures would probably not reduce the frequency of contrails. Hydrogen fuels would cause larger increases in local relative humidity in the exhaust plume causing higher supersaturations than would occur with hydrocarbon fuels. Thus, liquid hydrogen would probably cause more contrails to form, but possibly with greater particle sizes and fallout rates resulting in shorter lifetimes and less radiative impacts. It is possible that a propulsion source that does not require exhaust of water vapor will be necessary to effectively eliminate the generation of contrails from high flying aircraft.

Other methods to minimize contrail formation would involve changes in flight altitude or path. Contrail coverage could be reduced dramatically by flying in the stratosphere where contrail formation conditions are rare. However, other effects from the exhaust and increased fuel usage may limit the amount of stratospheric traffic. Flying at lower altitudes would diminish the number of contrails in tropical areas, but would cause additional coverage in the midlatitudes and polar regions. Conversely, higher mean flight altitudes would decrease contrails over the poles and temperate zones while causing more contrails in the equatorial areas. Ideally, numerical weather prediction models and contrail formation prognostication programs could be used together with flight planners to map out for each destination a sequence of flight altitudes that best avoids contrail formation conditions. Such planning could theoretically be used to neutralize the warming effect of contrails or even induce a small cooling. Such sophisticated planning would require more accurate temperature and humidity data and contrail prediction schemes than currently available as well as a more complex air traffic control network. Future research may provide the tools to minimize the climatic effects of

contrails, but it is likely that these artificial clouds will be a common feature in the sky for many years to come.

Cloud Microphysics

Synopsis

The microphysics of a cloud is concerned with the aqueous particles making up the cloud, how they are classified, and how they change with time. The particles, either liquid or solid (ice), vary greatly in size and shape, so mathematical methods are used to characterize them. The growth of cloud particles, as well as any transformation of phase, is determined by considering the physics of condensation, collision-coalescence, and nucleation. The diverse physical processes operate in a complicated dynamical environment to produce the precipitation that falls to the ground.

Introduction

Cloud microphysics is the branch of the atmospheric sciences concerned with the many particles that make up a cloud. Relative to the cloud as a whole, the individual particles are very small and so exist on the ‘microscale,’ that is, range over distances from fractions of a micrometer to several centimeters. The ‘microstructure’ of a cloud is a specification of the number concentrations, sizes, shapes, and phases of the various particles, factors that strongly influence the behavior of the particles and cloud lifetimes. The abilities of clouds in general to produce rain or snow, generate lightning, and alter the radiation balance of the earth, for instance, stem in large part from their individual microstructures working in concert with the local air motions. Cloud physicists characterize the diverse microstructures of atmospheric clouds and try to understand the processes that cause them to change with time.

Clouds typically form in response to changes in atmospheric conditions on scales much larger than those of the particles or, indeed, of the cloud itself. Synoptic-scale wind patterns and convection often force air to rise, which causes the pressure and temperature to decrease. This cooling during ascent leads to lowering of the equilibrium vapor pressures of the liquid and solid phases of water. ‘Excess’ vapor, that amount above the equilibrium value, thus develops and causes a state of disequilibrium to exist in the rising air parcels. Condensation is nature’s way of attempting to restore equilibrium.

A cloud, especially during its early stages of formation, often exhibits the properties of a colloidal system, a suspension of tiny particles that follow the air flow and interact only weakly with one another. Whereas the individual aqueous particles may form, grow, and subsequently disappear, the system as a whole remains microphysically stable for some time. The discipline of cloud microphysics helps us understand the specific mechanisms by which clouds form, break any colloidal stability, and form precipitation.

Microphysical Descriptions

The microstructure of a cloud may be categorized and described statistically in a number of ways. Empirical descriptions, typically derived from *in situ* or remotely sensed measurements of clouds, facilitate communications among

atmospheric scientists and provide the first glimpses of the physical processes operative at the time the measurements were taken. The microstructure may differ substantially from one part of a cloud to another, and it evolves with time in ways that depend on the environmental setting and the specific physical processes that are active at the time. Mathematical and numerical models, depending on their purpose, may employ the empirical descriptions directly, or they may calculate the time evolution of the microstructure if the relevant processes are included.

The particles in a cloud vary in phase, composition, size, and shape. The phase, whether solid or liquid, is the most fundamental descriptor of the aqueous particles, but the nonaqueous aerosol particles are also crucial to cloud formation and evolution. Liquid condensate forms preferentially on soluble ‘cloud condensation nuclei’ (CCN), which typically contain sulfates and nitrates. Ice particles, by contrast, often form on ‘ice nuclei,’ insoluble aerosol particles that contain crustal components or biological matter having crystalline structures related to that of ice. The dominant phase of the aqueous particles forms the basis for classifying clouds as ‘warm,’ when only liquid drops are present, or ‘cold,’ when ice is involved (with or without liquid drops). The ‘mixed-phase’ region of a cloud, throughout which both the liquid and solid (ice) phases of water may be present simultaneously, is that vertical zone between the melting level (0 °C) and the –40 °C isotherm, the practical lower limit for liquid water to exist in the metastable (i.e., ‘supercooled’) state. The relative abundance of each phase in a given cloud depends on the prevailing meteorological conditions and the microphysical processes active during the life cycle of the cloud.

The sizes and shapes of the aqueous particles play important roles in cloud development. Whereas ice particles can and do appear in a wide variety of shapes, all but the largest liquid drops tend to remain spherical because of surface tension effects. **Figure 1** depicts the various categories of liquid drops based on their sizes. Note that the size of a particle is an important determinant of its terminal fall speed and hence of its ability to fall against prevailing updraft speeds ($\sim 10 \text{ cm s}^{-1}$ in stratiform clouds; $\sim 10 \text{ m s}^{-1}$ in convective storms). Drizzle drops represent a transition between the small ‘droplets’ that follow the air motions and the larger drops that sediment and possibly reach the ground as rain. The shapes of bigger raindrops tend to become distorted because of the large dynamic

Figure 1 Various categories of liquid drops in clouds. The drops are drawn roughly to scale relative to each other, as are the arrows representing the terminal fall speeds. Representative magnitudes of drop radii (r) and fall speeds (v) are as indicated. The large raindrop is shown distorted to suggest the effect of dynamic pressure on its underside due to its fall through the air. 'CCN' represents a cloud condensation nucleus, a solution droplet that serves as the initial site of condensation.

pressure on the lower side, giving the rough appearance of a ball of dough pressed lightly onto a tabletop. This flattening of the underside causes the aerodynamic resistance to be larger than that of spherical drops of equivalent volume and so limits the fall speeds of raindrops to about 10 m s^{-1} .

The ice particles in a cloud vary enormously in both size and shape. The first ice to appear in many clouds tends to be small ($\sim 10 \text{ μm}$ across) and monocrystalline in structure. Single crystals of ice subsequently grow into hexagonal prisms (each prism being bounded by two 'basal' faces and six 'prism' faces) with axial ratios (length along the principal or ' c ' axis divided by the ' a ' axis, the width across the corners of the hexagon) that depend systematically on the temperature. As shown in **Figure 2**, 'plates' (c/a axial ratios less than unity) are found when the temperature is either between 0 and about -3°C or between about -8 and -22°C . On the other hand, 'columns' ($c/a > 1$) appear in the approximate temperature ranges -3 to -8°C and less than -22°C . Deviations from simple hexagonal prisms are common and depend on the excess vapor density, as suggested by the various symbols in **Figure 2**. In addition to the many single crystals, a number of polycrystalline forms of ice are found in cold clouds. For instance, several to hundreds of single crystals may clump together to form 'aggregates' (i.e., snowflakes), and supercooled cloud droplets may freeze onto ice particles, giving rise to rimed crystals, graupel, and hail.

Figure 2 Schematic representation of the wide variations in the shapes ('habits') of ice crystals found in clouds at the indicated temperatures and excess vapor densities (relative to the ice phase). The excess vapor density of air saturated with respect to supercooled liquid water is shown by the dashed curve. The heavy dashed lines identify the approximate temperatures at which the primary habits change between plates and columns. The diagram has been oriented to suggest the normal decrease of temperature with altitude.

Individual crystals seldom grow to more than a few millimeters across, but hailstones can sometimes exceed 10 cm in diameter.

The cloud microstructure is best viewed as a multidimensional specification of the number concentrations of the various particles in a cloud. In the case of liquid drops, one needs to consider only the sizes of the drops and how they vary in space and time. The nonspherical ice particles, by contrast, require additional specification, such as axial ratio, to account for the shapes of the particles. 'Spectral' descriptions of the cloud particles tell us in effect how many of what kinds and sizes of particles are present at given locations within a cloud.

Often, it is useful to characterize the spectra in mathematical terms to minimize the number of variables needed to represent the microstructure. The size distributions of raindrops from convective storms, for example, can be described by analytical functions that have been fitted to observational data by specifying two or three parameters, as shown in **Figure 3**. An exponential function, one subclass of which is referred to as a 'Marshall–Palmer' distribution, has the form

$$n(D) = n_0 \exp(-\lambda D) \quad [1]$$

where n_0 and λ are the parameters fitted to the measured number concentration $n(D)$ of drops within a unit size interval about diameter D . Exponential distributions are used frequently because only two parameters (here, n_0 and λ) need to be specified. However, as the heavy dotted line in **Figure 3** shows, exponential distributions often overestimate the

Figure 3 The size distribution of raindrops from a convective storm. Circles: calculated values based on 1-min samples from a 20-channel disdrometer. Dotted line: an exponential fit to the data. Dot-dashed curve: a modified gamma function. Solid curve: log-normal function. Adapted from Feingold, G., Levin, Z., 1986. The lognormal fit to rain-drop spectra from frontal convective clouds in Israel. *Journal of Applied Meteorology and Climatology* 25, 1346–1363.

number of smaller drops. A more general form, the modified gamma distribution,

$$n(D) = n_0 D^\mu \exp(-\lambda D) \quad [2]$$

attempts to correct this deficiency, although at the expense of requiring an additional parameter (μ). At least for the data shown in Figure 3, a log-normal function of the form

$$n(D) = \frac{N_T}{\sqrt{2\pi D \ln \sigma_g}} \exp(-\ln^2(D/D_g)/2 \ln^2 \sigma_g) \quad [3]$$

works well with appropriate choices of the three parameters: total number concentration N_T , geometric median diameter D_g , and geometric standard deviation σ_g . It is important to recognize that empirical size spectra simply describe the cloud microstructure without regard to the mechanisms that produced it.

Warm-Cloud Microphysics

The liquid drops in ‘warm’ clouds evolve spectrally via microphysical processes that interact in complicated ways with the

larger scale cloud environment. The process of condensation, for instance, starts during upward motion of moist air and continues even as the drops interact with themselves and grow into raindrops. As the cloud updraft entrains dry environmental air, ceases, or possibly reverses, evaporation may dominate for a time and change the microstructure in important ways. The ever-changing population of drops often influences the very atmospheric motions that spawned the drops in the first place.

Droplet Formation

The many small droplets in a cloud form initially as excess vapor condenses onto the larger, more soluble aerosol particles (i.e., onto the CCN). The solute in the CCN lowers the equilibrium vapor pressure of the liquid droplets through molecular scale effects, whereas the droplet curvature increases it.

The two opposing effects of solute and curvature are typically combined in Köhler theory to yield the equilibrium saturation ratio S_K as a function of the droplet radius r :

$$S_K = a_w \cdot \exp(A/r) \quad [4]$$

Here, the first factor on the right-hand side of eqn [4] describes the vapor pressure lowering effect of the solute in terms of the water activity $a_w = 1 - ix_s$, where x_s is the mole fraction of nonvolatile solute that effectively dissociates into i molecular or ionic components. The second factor in eqn [4] accounts for the effect of droplet curvature on vapor pressure, where $A = 2\sigma_{LV}/(n_L RT)$ is a function of the physically relevant variables, the liquid–vapor surface free energy σ_{LV} ($= 72 \text{ mJ m}^{-2}$), the liquid water density n_L ($= 5.5 \times 10^4 \text{ mol m}^{-3}$), the universal gas constant R ($= 8.31 \text{ J mol}^{-1} \text{ K}^{-1}$), and the temperature T . Because each droplet grows by the sole addition of water, its total solute content N_s remains constant and the solute mole fraction $x_s = N_s/(n_L V_d)$ decreases as the droplet grows in volume $V_d = 4\pi r^3/3$. Equation [4] can thus be expressed in terms of the supersaturation s_K needed to maintain equilibrium with the solution droplet:

$$s_K \equiv S_K - 1 = \frac{A}{r} - \frac{BiN_s}{r^3} \quad [5]$$

where $B = 3/(4\pi n_L)$ and approximations suitable for initial cloud formation have been made. Equation [5] can be seen to represent a family of ‘Köhler’ curves, each of constant solute content. The competing effects of solute and curvature yield a maximum in the equilibrium saturation ratio, as shown in Figure 4. The solute effect predominates at small sizes, whereas the curvature effect predominates at large sizes. The maximum value, termed the critical supersaturation, must be overcome by the ambient supersaturation before the particle can ‘activate’ and grow spontaneously as a cloud droplet. The critical supersaturation, found mathematically by setting the first derivative of s_K equal to zero, decreases as the solute content increases:

$$s_c = \left(\frac{4A^3}{27BiN_s} \right)^{1/2} \quad [6]$$

The larger the aerosol particle, the smaller is the ‘critical supersaturation’ that needs to be exceeded. Note that the

Figure 4 A set of Köhler curves. Each curve represents the saturation ratio of vapor needed to maintain equilibrium with solution drops containing the indicated solute contents.

critical supersaturation, $s_c \propto 1/N_s^{1/2} \propto 1/r^{3/2}$, is especially large for particles with the smallest solute contents, so small aerosol particles may never experience sufficiently high ambient supersaturations to become activated. Such small particles remain as submicron haze droplets interstitially between the much larger cloud droplets.

Growth by Condensation

Each cloud droplet acts as a tiny sink of water vapor during active growth in an updraft. As condensation proceeds, the concentration of vapor immediately over each droplet surface (within a few mean free paths of the air molecules) is reduced relative to the average vapor concentration far from the droplet. The radial gradients of vapor concentration thus established give rise to a net flux of vapor molecules toward the drop by the process of molecular diffusion. The water molecules must also be transported across the liquid–vapor interface, but it is the vapor diffusion step that tends to limit the mass transport under most cloud conditions. Nevertheless, the change of phase from vapor to liquid at the surface results in a slight warming of the droplet due to the added enthalpy of condensation, energy that must be conducted away from the droplet through the air. This energy consequence of condensation raises the equilibrium vapor pressure of the liquid and imposes an additional limitation to the growth rate.

The theory that simultaneously accounts for the exchanges of vapor and energy between a growing droplet and the surrounding air was first developed fully by Maxwell in the nineteenth century. The resulting expression for the linear growth rate is

$$\frac{dr}{dt} = G(s - s_K) \frac{1}{r} \quad [7]$$

where G is a growth parameter that acts as an effective diffusivity and varies slowly with the temperature and pressure. Note that a droplet grows only to the extent that the ambient supersaturation (s) exceeds the equilibrium value (s_K). As r becomes large, $s_K \rightarrow 0$ and the growth rate $dr/dt \propto 1/r$, indicating that the droplets grow relatively more slowly as they become larger.

A population of growing cloud droplets obtains its water from a common supply, namely the vapor initially carried with the rising air parcel. Competition for the available vapor among all the droplets sets up a strong interplay between the condensation kinetics, the aerosol population, and the vapor field. Results from numerical computations of droplet growth within an air parcel rising adiabatically are shown in [Figure 5](#) for the case of a relatively clean maritime environment. The ambient supersaturation (dashed curve) builds up in the rising parcel because of the decrease in temperature with height and the consequent lowering of equilibrium vapor pressure. Aerosol particles with relatively large solute contents, those having low critical supersaturations, activate and become cloud droplets that grow rapidly (seen in [Figure 5](#) by the sudden changes in slope). Condensation onto the activated droplets removes water vapor from the air, so the supersaturation increases progressively more slowly as the droplets grow and deplete the vapor. At some point, usually within several meters above cloud base, the rate of vapor removal exceeds the rate at which excess vapor is generated, and the supersaturation then steadily decreases. The maximum supersaturation, $s_{\max}$, attained in the cloud is influenced strongly by the abundance of aerosol particles and becomes an important determinant of the microstructure of warm clouds. Once the maximum in the supersaturation is reached, no new particles can be activated. The initial number concentration of cloud droplets is thus established low in the cloud and reflects the properties of the aerosol population present at the time of cloud formation.

The interaction between the aerosol population and the vapor field can be understood with the help of [Figure 6](#) (also available as a sequence of PowerPoint slides in the supplementary material). Early in the evolution of supersaturation, say at point 1 in panel (a), the only particles that can activate

Figure 5 Results from numerical calculations of activation and growth of droplets in an air parcel ascending adiabatically at the rate of 15 cm s^{-1} . The total concentration of particles is 50 cm^{-3} . Solid curves: droplet radii (lower scale) at various heights above cloud base for droplets containing the indicated solute contents (number of moles of nonvolatile solute per particle). Dashed curve: ambient supersaturation (upper scale). Adapted from Mordy, W., 1959. Computations of the growth by condensation of a population of cloud droplets. *Tellus* 11, 16–44.

Figure 6 Graphical relationships between the evolution of ambient supersaturation in an adiabatically ascending parcel (panel a), the critical supersaturations of individual aerosol particles (b), and the size distributions of the aerosol number and volume concentrations (c). The circled numbers show specific values of each variable at selected supersaturations; the shaded regions identify portions pertaining to the activated aerosol after the supersaturation has reached its maximum value (s_{max}).

are those with small critical supersaturations (corresponding point in panel (b)). Such particles are relatively large and so have large solute contents. These initially activated particles typically reside in the tail of the aerosol size distribution ('Number' curve in panel (c)) and so represent only a small fraction of the total aerosol population. However, these are the largest particles and so represent a significant fraction of the total solute incorporated into the cloud water (see 'Volume' curve in panel (c)).

As the supersaturation continues to increase (e.g., point 2 in panel (a) of Figure 6), progressively smaller particles (those with increasing critical supersaturations; panel (b)) are activated and added to the population of droplets. The greater the number of growing droplets, the greater are the opportunities for vapor to be consumed. Once the maximum supersaturation has been reached (point 3 in panel (a)), all the particles that can be will have been activated. The limiting diameter of the dry aerosol particles activated, those with critical supersaturations equal to or less than the maximum ambient supersaturation, is called the activation diameter (D_{act}). With additional uplift of the cloud parcel, the supersaturation decreases (e.g., point 4) below the critical supersaturations of the remaining particles in the aerosol population. The inactivated set of particles is the haze droplets and the activated set, the cloud droplets. As long as the air continues to rise, the supersaturation stays positive, and the activated droplets continue to grow.

The close packing of the curves near the top on the right-hand side of Figure 5 is consistent with eqn [7] and indicates

that the droplets tend to bunch together in radius. This narrowing of the drop spectrum is an inherent property of adiabatic condensation and poses a hindrance to the formation of precipitation. Detailed calculations show that individual droplets experiencing a supersaturation of 1% require hundreds of seconds to grow by condensation to radii much beyond $10 \mu\text{m}$. Significant additional growth depends on collisions between particles.

Collisional Interactions

Individual pairs of cloud drops occasionally collide with one another. If two drops 'coalesce' during a particular collision, a single, larger drop replaces the two parent drops in the cloud. Repeated collision-coalescence events eventually lead to large drops that fall rapidly and become raindrops.

The growth of drops through collisional interactions may be quantified by considering the separate probabilities for collision and for coalescence. Most commonly, collisions result when a larger drop (the 'collector' drop) overtakes a smaller drop (the 'collected' drop) during its fall through the air. However, not all drops in the geometrical path of the collector experience collisions, for the simple reason that the air deviating around the collector drop 'pushes' the smallest drops out of the way. The fraction of drops in the path of the collector that do collide with it is the 'collision efficiency' (E), a complicated function of both the collector- and collected-drop sizes. The maximum collision efficiency can approach unity when the

collector-drop radii are greater than about 40 μm and the collected-drop radii exceed about 5 μm . However, for collector-drop radii less than about 20 μm , the collision efficiency becomes very small. The ‘coalescence efficiency’ (ϵ), the fraction of drop–drop collisions actually resulting in the formation of a larger drop, is often less than unity for larger collected drops because of drop distortion and the trapping of air at the point of collision. The ‘collection efficiency’ (E_c) is the product of the collision and coalescence efficiencies, $E_c = E \cdot \epsilon$, and typically reaches a weak maximum at intermediate collected-drop radii. The collection efficiency provides an overall indication of the effectiveness of drop growth by collision–coalescence.

Collision–coalescence becomes a powerful mechanism for generating raindrops under appropriate microphysical conditions. Because of the *de facto* thresholds that exist on both the collected- and collector-drop sizes, collision–coalescence tends to begin in the tail of the cloud-drop size distribution. Initially, only a tiny fraction of the bigger droplets will collide and coalesce with neighboring droplets, yielding slightly larger droplets that then have enhanced probabilities of collecting additional droplets. The growth process accelerates as the collection efficiencies increase and other drops join this favored subset of the drop population. Eventually, a new mode in the drop-size distribution emerges, as shown by the maxima toward the right-hand side of Figure 7. Once the drops in this large-drop mode exceed a few hundred microns, they grow rapidly in mass at a more-or-less continuous rate given by

$$\frac{dm}{dt} = K(r_1, r_s) \cdot \omega_L \quad [8]$$

where $K(r_1, r_s) = \pi(r_1 + r_s)^2 E_c \cdot (v_1 - v_s)$ is the collection kernel and ω_L is the liquid water concentration (mass per unit volume of cloudy air). The collection kernel is best viewed as the effective volume of cloudy air (containing small droplets of radius r_s , each falling at rate v_s) that is swept out in unit time by the collector drop of radius r_1 having fall speed v_1 . In this continuous-growth regime (in which $r_s \ll r_1$, $v_s \ll v_1$, $v_1 \propto r_1$, and $E_c \cong 1$), one finds to first approximation $dm/dt \propto r_1^3 \propto m$. Thus, once the collision–coalescence process gets started, the large drops increase in mass (and size) exponentially with time, until the supply of cloud droplets is exhausted or the drops rupture and disperse as many smaller drops.

Figure 7 Evolution of the size distribution of drops undergoing collision–coalescence. Adapted from Berry, E. X., Reinhardt, R. L., 1974. An analysis of cloud drop growth by collection: Part II. Single initial distributions. *Journal of Atmospheric Sciences* 31, 1825–1831.

Cold-Cloud Microphysics

Clouds are classified as ‘cold’ once ice particles form and become active players in the cloud microphysics. Whereas ice particles are necessary components of cold clouds, the liquid drops are nevertheless often present and important to the evolution of the cloud microstructure. The mixed-phase zone of a cloud, where the ice particles and liquid drops interact, is microphysically the most active portion of a cloud. ‘Glaciation,’ the transformation of a cloud from supercooled liquid drops to ice particles, is complicated by the diversity of interactions that can take place.

Ice Formation

Ice can form once the liquid drops have become supercooled by at least 5 °C, even though the supercooled state can persist in some clouds to temperatures as low as –40 °C. The first ice particles in a supercooled cloud most commonly appear when the temperature is between –10 and –15 °C following ‘primary nucleation,’ a process by which submicron, insoluble aerosol particles catalyze ice formation by acting as molecular templates for the crystal lattice. Such primary ice particles may form directly from the vapor phase (via ‘deposition nucleation’), but more commonly they arise from the freezing of supercooled cloud droplets (via ‘freezing nucleation’). The freezing of droplets at relatively high temperatures (greater than about –18 °C) tends to yield single crystals that subsequently grow into crystallographically aligned double plates. At lower temperatures, however, the probability of forming multiple crystals within a single droplet becomes large, giving rise to polycrystalline forms, such as bullet rosettes.

Some ice particles form because of the prior existence of other ice particles. Such ‘secondary’ ice particles arise via several mechanisms, none of which are fully understood. In some situations, crystals may ‘fragment,’ such as when the delicate arms of dendrites break off, thereby increasing the ice particle number concentration. When conditions are just right, as when the temperature is between about –3 and –8 °C and ‘graupel’ particles are actively growing by riming (i.e., accreting supercooled cloud water), tiny splinters of ice may be released that subsequently grow into columnar ice crystals. The self-breeding, or ‘multiplication’ of ice seems to be important in clouds that glaciate rapidly.

Growth by Vapor Deposition

Individual ice particles grow initially by the deposition of vapor onto their surfaces. As with the growth of a cloud droplet by condensation, water molecules must first diffuse to the particle surface from the supersaturated vapor field surrounding the particle. However, the transport of molecules across the vapor–solid interface cannot be ignored, if for no other reason than the need to account for facets and the nonspherical shapes of the ice particles. The molecular scale processes on the crystal surface involve migration of molecules across the surface, from the point of first contact to a step that may be a micron or more away. As the step gathers adsorbed molecules, it propagates across the surface, contributing an additional layer (of thickness equal to the step height) of molecules to the lattice.

The rate of advancement of the crystal face is determined largely by the frequency with which the steps are generated, a factor that depends on whether the steps originate from two-dimensional layer nucleation or from the emergence of screw dislocations on the surface.

The aspect ratio of an ice crystal reflects the relative rates of growth of the basal and prism faces. For reasons that remain largely unknown, the linear growth rates vary with the temperature in complicated ways, giving rise to the observed alternation of primary habit between plates and columns with temperature (as depicted in [Figure 2](#)). At relatively large supersaturations with respect to ice, the vapor gradients in the vicinity of a given crystal face become important, leading to the bunching of steps, 'hollowing' of the face near its center, and a myriad of secondary habit features superimposed on the primary habit. Good physical reasons exist why one seldom if ever finds any two ice crystals alike in nature.

Riming and Aggregation

Riming and aggregation are both processes involving collection. As in warm clouds, collisions between particles must first occur and then the colliding particles must stick together to form a combined particle. In the case of riming, an ice particle collects supercooled droplets that freeze on contact with the ice surface. By contrast, aggregation involves the collisional interaction of two ice particles, with no change of phase. Aggregation is a complicated process, in part because snowflakes fall erratically and because two solid particles may simply bounce apart after colliding. Snow crystals are most likely to stick together at temperatures within a few degrees of the melting point (because of sintering), or when the arms of dendrites can interlock.

Growth via the riming process occurs by stages that depend on particle size and the rate at which supercooled droplets are accreted. Initially, during the 'crystal stage,' the rate of accretion is slow, the collision efficiency becoming appreciable only once the vapor-grown crystal attains an *a*-axis dimension of about 150 μm for plates, 25 μm for columns. The crystal becomes lightly to moderately rimed, but the crystal morphology remains identifiable. Such growth is termed 'dry' because each droplet freezes rapidly at the spot of impingement. The 'graupel stage' begins once the crystal identity becomes obscured by the shroud of 'dry' rime ice on the particle. During this and the subsequent 'hail stage,' the ice particle grows in mass at rates described reasonably well by [eqn \[8\]](#), with suitable adjustments in the parameters. The hail stage is distinguished from the graupel stage by the formation of one or more layers of clear ice, which results when the rate of accretion exceeds the ability of the particle to dissipate the enthalpy added by the freezing of the supercooled water. Such 'wet' growth occurs when the surface temperature rises to 0 $^{\circ}\text{C}$ and the accreted liquid spreads across the surface before freezing. Hailstones represent one extreme to which the microstructure of clouds can evolve.

Precipitation

Precipitation, whether in the form of rain, snow, sleet, or hail, generally results once the aqueous particles in a cloud

have grown sufficiently large to fall against the local updraft. In the case of a stratiform cloud, one characterized by rather weak and uniform updrafts over a broad area, the precipitating particles may simply fall out through the base of the cloud, in the process depleting condensate from the cloud and depositing it on the ground. On the other hand, in convective storms, in which large local updraft speeds can aerodynamically support big particles, the precipitation itself may influence the motions of air through the cloud. The large mass associated with the precipitation commonly initiates a downdraft along the edge of the updraft, causing the microphysical and dynamical aspects of cloud evolution to become intertwined in complicated ways. As an aid to the discussion below, [Figure 8](#) offers a summary of the various processes operating in the 'warm' and 'cold' parts of a representative convective cloud during precipitation formation.

In the warm parts of clouds, large drops can emerge out of the stable population of cloud droplets only through collisional interactions. Condensational growth alone is too slow, but it must be recognized as a necessary process, for the numerous cloud droplets serve as the feedstock for the growth of the larger drops. The collision-coalescence process becomes an effective mechanism for breaking the colloidal stability of the cloud once the threshold size ($\sim 25 \mu\text{m}$ diameter) for collection has been overcome. The needed 'coalescence embryos' can arise from the droplet population itself (most commonly in clean, maritime environments or during turbulent mixing), alternatively from 'giant nuclei' in dusty regions. Once the warm-rain mechanism is established, the raindrops grow rapidly by sweeping out the smaller cloud droplets until they themselves become unstable and rupture into fragments during their fall to earth.

In the cold parts of a cloud, the colloidal stability of the cloud is broken once the ice phase has been nucleated in the presence of supercooled droplets. This 'ice-crystal' mechanism, often termed the Bergeron process, arises from the inherent difference in the equilibrium vapor pressures of liquid and solid water. The relatively low vapor pressure of ice compared with that of the droplets at any given temperature gives the ice crystals a growth advantage by causing water vapor to transfer (via diffusion) from the many cloud droplets to the fewer ice crystals. The process proceeds rapidly, especially in the temperature range between -12 and -18°C , permitting the ice crystals to attain sizes sufficient to initiate the other cold-cloud growth mechanisms, such as aggregation and riming. These large ice particles eventually fall into the warm part of the cloud, where they may melt and join the population of raindrops formed by the collision-coalescence process. The ice process can be an effective initiator of precipitation in both stratiform clouds and summer thundershowers.

The efficiencies with which clouds develop precipitation depend partly on the types of microphysical processes that are active and partly on the environmental settings in which the clouds form. For instance, the relative ease with which 'maritime' clouds release precipitation compared with 'continental' clouds most likely stems from the differences in aerosol abundance found in the different air masses. The relative absence of active sources of aerosol particles over the open

Figure 8 Summary of microphysical processes operating inside a deep convective cloud.

oceans leads to low CCN concentrations, which in turn means that those few droplets that do form in maritime clouds tend to grow faster on average than do those in continental clouds. The collision-coalescence process thus gets started early in the life cycle of maritime clouds, providing such clouds with a decisive microphysical mechanism for developing precipitation. Within a given climatic regime, storm organization on the mesoscale seems to be an important contributor to precipitation efficiency. Small magnitudes of vertical wind shear at the time of cloud formation tend to favor vertically erect storms with high precipitation efficiencies, presumably because the incipient precipitation particles can then fall directly through the condensate-rich inflow of the storm. At the same time, however, such systems tend to be short lived and yield relatively small total amounts of precipitation. Storms that form in environments in which the wind varies modestly with height in both speed and direction last longer and yield the most precipitation, for then synergism arises between the dynamical time scales of the storm and the time scales for the microphysical processes to operate effectively.

Synopsis

The history of how clouds came to be named and what those names are is reviewed. The typical visual and microstructural attributes of the 10 cloud genera and their most commonly seen species or varieties are accompanied by a short cloud pictorial atlas.

Introduction

Official synoptic weather observations, available for more than 70 years at weather observing stations around the world, have contained information on the coverage of various types of clouds based on a classification system that was largely in place by the late 1890s. Cloud observations have had increased value in recent years besides their traditional role in helping to assess the current condition of the atmosphere; those observations are now also seen as providing a long-term record from which changes in cloud coverage and type associated with climate change might be discerned that are not detectable in the relatively short record of satellite data. This article discusses what a cloud is, the origin of the classification system of clouds that is used today, and contains photographs of the most commonly seen clouds.

What Is a Cloud?

As defined by the World Meteorological Organization (WMO, 1969), a cloud is 'an aggregate of minute, suspended particles of water or ice or both that are in sufficient concentrations to be visible'; a collection of 'hydrometeors,' a term that also includes in some cases, due to perspective, the precipitation particles that fall from them.

Clouds are tenuous and transitory; no single cloud element, even within an extensive cloud shield, exists for more than a few hours, and most small clouds in the lower atmosphere exist for only a few minutes. And, in precise numbers, the demarcation between a cloud and clear air is hard to define: How many cloud drops per liter constitute a cloud? When are ice crystals and snow termed 'clouds' rather than precipitation? When are drops or ice crystals too large to be considered 'cloud' particles but rather 'precipitation' particles?

These questions are difficult for scientists to answer in unanimity because the difference between cloud particles and precipitation particles, for example, is not black and white rather they represent a continuum of fall speeds. For some scientists, a 50- μm diameter drop represents a 'drizzle' drop because it must have formed from collisions with other drops, but for others, it may be termed a 'cloud' drop because it falls too slowly to produce measurable precipitation and evaporates almost immediately after exiting the bottom of the cloud. Also, the farther an observer is from falling precipitation, the more it appears to be a 'cloud' due to perspective. For example, many of the higher 'clouds' seen above, such as cirrus and altostratus

clouds, are composed mainly of ice crystals and even snowflakes that are settling toward the earth; they would not be considered a 'cloud' by an observer inside them on Mount Everest, for example, but rather a very light snowfall.

Origin of the Present-Day Cloud Classification System

The classification system for clouds is based on what was seen above. The process of classifying objectively the many shapes and sizes of something as ephemeral as a cloud was first accomplished at about the same time at the turn of the nineteenth century by an English chemist, [Luke Howard in 1803](#) and a French naturalist, Jean Baptiste Lamarck in 1802. Both published systems of cloud classifications. However, because Howard used Latin descriptors of the type that scientists were already using in other fields, his descriptions appeared to resemble much of what people saw, as did Lamarck's, and because he published his results in a relatively well-read journal, *Tilloch's Philosophical Magazine*, Howard's system became accepted and was reproduced in books and encyclopedias soon afterward.

Howard observed, as had Lamarck before him, that there were three basic cloud regimes. There were fibrous and wispy clouds that Howard called 'cirrus' (Latin for hair); sheet-like laminar clouds that covered much or all of the sky that he referred to as 'stratus' (meaning flat); and clouds that were less pervasive but had a strong vertical architecture that he called 'cumulus' (meaning 'heaped up'). Howard used an additional Latin term 'nimbus' (Latin for cloud) meaning in this case, a cloud or system of clouds from which precipitation fell. Today, nimbus itself is not a cloud but rather a prefix or suffix to denote the two main precipitating clouds, nimbostratus and cumulonimbus. The question over clouds and their types generated such enthusiasm among naturalists in the nineteenth century that an ardent observer and member of the British Royal Meteorological Society, Ralph Abercromby, took two voyages around the world to make sure that no cloud type had been overlooked!

The emerging idea that clouds preferred just two or three levels in the atmosphere was supported by measurements using theodolites and photogrammetry to measure cloud height at Uppsala, Sweden as well as at sites in Germany and in the United States in the 1880s. These measurements eventually led H. Hildebrandsson, Director of the Uppsala Observatory, and Abercromby to place the 'low,' 'middle,' and 'high' cloud groupings of Howard more systematically in their

own 1887 cloud classification. At this time, cumulus and cumulonimbus clouds were placed in a fourth distinct category representing clouds with appreciable updrafts and vertical development.

Howard's modified classification system was reexamined at the International Meteorological Conference at Munich in 1891 followed by the publication of a color cloud atlas in 1896. At this point, the definitions of clouds were close to their modern forms. Additional international committees made minor modifications to this system in 1926 that were realized with the publication of the 1932 International Cloud Atlas. Little change has been made since that time. Perhaps the most noticeable change was to move thick layers of altocumulus (opacus), a cloud comprised of mostly or completely of droplets, out of the altostratus domain and into the altocumulus domain. Altostratus was then confined to clouds mostly or completely comprised of ice, but unlike cirriform clouds are generally thick enough to produce shading. Altostratus, like cirrostratus, usually covers most of the sky if not all of it.

The most comprehensive version of the cloud classification system was published by the WMO in 1956 in two volumes entitled 'The International Cloud Atlas, Volumes I and II.' Volume I contained the cloud morphology, while Volume II consisted of photographs. An abridged *International Cloud Atlas* was published in 1969. This Atlas combined morphology and photographs. The cloud morphology volume (Volume I) was published again in 1975 by the WMO. In 1987, a revised Volume II of photographs was published that included photographs of clouds from more disparate places other than in the previous volumes. However, there was some lack of consistency in classifying clouds compared with the earlier Volume II. Care should be taken when using the 1987 revised version.

The Classification of Clouds

There are 10 main categories or 'genera' into which clouds are classified for official observations. These 10 categories are cirrus, cirrostratus, cirrocumulus, altostratus, altocumulus, nimbostratus, stratocumulus, stratus, cumulus, and cumulonimbus. **Table 1** is a partial list of the nomenclature used to describe the most commonly seen species (defined by overall shapes) and varieties (defined by arrangements of subelements of the clouds) of these genera. **Figures 1–25** illustrate these most frequently seen forms.

Within these 10 categories are three cloud base altitude regimes. They are 'high' clouds, those with bases generally above 7 km above ground level (AGL); 'middle-level' clouds, those with bases between 2 and about 7 km AGL; and 'low' clouds, those with bases at or below 2 km AGL. The word 'about' is used because clouds with certain visual attributes that make them, for example, a 'middle-level' cloud may actually have a base that is above 7 km. Similarly, in winter-time or in the arctic, 'high' clouds with cirriform attributes (fibrous and wispy) may be found at heights below 7 km. Also, some clouds that are still considered low clouds (e.g., cumulus clouds) can have bases that are a kilometer or more above the general 'low cloud' upper base limit of 2 km AGL. Therefore, these cloud base height boundaries should be

Table 1 The 10 cloud types and their most common species and varieties. After the World Meteorological Organization, 1975. The letters in parentheses denote accepted abbreviations

Genera	Species	Varieties
Cirrus (Ci)	Uncinus, fibratus, spissatus, castellanus	Intortus, radiatus, vertebratus
Cirrostratus (Cs)	Nebulosus, fibratus	
Cirrocumulus (Cc)	Castellanus, floccus, lenticularis	Undulatus
Alto cumulus (Ac)	Castellanus, floccus, lenticularis	Translucidus, opacus, undulatus, perlucidus
Altostratus (As)	None	Translucidus, opacus
Nimbostratus (Ns)	None	None
Stratocumulus (Sc)	Castellanus, lenticularis	Perlucidus, translucidus opacus
Stratus (St)	Fractus, nebulosus	
Cumulonimbus (Cb)	Calvus, capillatus	
Cumulus (Cu)	Fractus, humilis, mediocris, congestus	

considered somewhat flexible. Note, too, that what is classified as an altocumulus layer when seen from sea level, will be termed a stratocumulus layer when the same cloud is seen by an observer at the top of a high mountain because the apparent size of the cloud elements, part of the definition of these clouds, becomes larger, the nearer one is to the cloud layer.

The classification of clouds is also dependent on their composition. This is because the composition of a cloud, all liquid, all ice, or a mixture of both, determines many of its visual attributes on which the classifications are founded (e.g., luminance, texture, color, opacity, and the level of detail of the cloud elements). For example, an altocumulus cloud cannot contain too many ice crystals and still be recognizable as an altocumulus cloud. It must always be composed largely of water drops to retain its sharp-edged compact appearance. Thus, it cannot be too high and cold. On the other hand, fibrous trails of ice crystals comprising cirrus clouds cannot be too low (and thus, too warm). Therefore, having the ability to assess the composition of clouds (i.e., ice vs. liquid water) visually can help in the determination of a cloud's height.

Other important attributes for identifying a cloud are How much of the sky does it cover? Does it obscure the sun's disk? If the sun's position is visible, is its disk sharply defined or just a bright spot? Does the cloud display a particular pattern such as small cloud elements, rows, billows, or undulations? Is rain or snow falling from it? If so, is the rain or snow falling from it concentrated in a narrow shaft, suggesting towering cloud tops above, or is the precipitation widespread with little gradation, a characteristic that suggests uniform cloud tops? Answering these questions will allow the best categorization of clouds into their 10 basic types.

High Clouds

Cirrus, cirrostratus, and cirrocumulus clouds (**Figures 1–5**, respectively) comprise 'high' clouds. By WMO definition, they

Figure 1 Cirrus uncinus.

Figure 2 Cirrus spissatus.

are not dense enough to produce shading except when the sun is near the horizon, with the single exception of a thick patchy cirrus species called cirrus spissatus ([Figure 2](#)) in which gray shading is allowable. (Many users of satellite data refer to

'cirrus' or 'cirriform' those clouds with cold tops in the upper troposphere without regard to whether they produce shading as seen from below. However, many such clouds so described would actually be classified as 'altostratus' clouds by ground

Figure 3 Cirrostratus nebulosus (smooth regions); Cirrostratus fibratus (region with lines).

Figure 4 Cirrocumulus (lower warmer version, right third of photo above and to the right of the palm tree, droplet composition).

observers due to the gray shading they produced.) Cirrus (Figures 1 and 2) and cirrostratus (Figure 3) clouds are composed of ice crystals with, perhaps, a few momentary exceptions at formation when the temperature is higher than

−40 °C. In these cases, droplets may be briefly present at the instant of formation. The ‘bases’ or visual bottoms of cirrus and cirrostratus clouds are composed of generally low concentrations of ice crystals that are about to evaporate. They are usually

Figure 5 Cirrocumulus (high and very cold; composed of ice soon after formation, as has occurred above and to the right of the antenna).

colder than -20°C . The coldest cirriform cloud tops (i.e., cirrus and cirrostratus) can be -80°C or lower in deep storms with high cloud tops such as in anvils associated with exceptional thunderstorms.

Cirrus and cirrostratus clouds are fibrous, wispy, and diffuse because the concentrations of ice crystals that comprise them are relatively low (from less than 1 per liter to tens per liter) compared with particle concentrations in other clouds. An exception to this is at the moment of formation when a spec or small, hard looking tuft of cirrus can have many thousands per liter of tiny quasispherical ice crystals which then gradually disperse after the moment of formation.

The long, usually curved filaments that often comprise cirriform clouds are caused by the growth of larger ice crystals that fall out into regions of changing wind speeds and directions below the parent cloud. Due to the slow settling of ice crystals, and depth of moist air below the formation level, mature cirrus and cirrostratus clouds are often 1 km or more thick though the sun may not be appreciably dimmed.

Haloed are usually seen with cirrostratus clouds, and occasionally, partial haloed are seen with cirrus clouds. Cirrus

clouds do not usually produce full haloed due to their patchy nature. In contrast, thicker ice clouds, such as altostratus (Figures 11 and 12), cannot produce haloed when seen from the ground. This is because while cirrus and cirrostratus clouds usually contain small, hexagonal ‘prism’ crystals such as thick plates, short solid columns – simple crystals that refract the sun’s light as it passes through them, deeper altostratus clouds generally have larger more complicated crystals and snowflakes that do not permit simple refraction even when the sun’s position is plainly evident.

The appearance of cirrostratus clouds in wintertime in the middle and northern latitudes, with its typical halo, has long been identified as a precursor to steady rain or snow.

Cirrocumulus (Figure 4 shown with altocumulus for comparison) clouds are patchy, finely granulated clouds. The largest of the visible cloud elements in cirrocumulus can be no larger than the width of a finger held skyward when observed from the ground; if larger, the cloud is classified as an altocumulus. Due to a definition that allows no shading, cirrocumulus clouds are very thin (less than 200 m thick), and usually very short-lived, often appearing and disappearing in minutes.

Figure 6 Altocumulus opacus.

Figure 7 Altocumulus perlucidus.

Cirrocumulus clouds, contrary to many descriptions of them found elsewhere, are generally composed mostly of or completely of water droplets, not ice crystals. This is because they generally occur at higher temperatures and lower

altitudes than cirrus and cirrostratus clouds. The fine granulation of cirrocumulus in isolation in the sky often leads to a misperception of much greater height of that cloud than where they are actually located. In fact, they are often

Figure 8 Altocumulus castellanus.

Figure 9 Altocumulus floccus virgae.

located (as shown in [Figure 4](#)) in what otherwise would be termed the 'midlevels' rather than a cirrus or 'high levels' as often thought, and altocumulus clouds are even present at the same level!

The liquid phase of cirrocumulus clouds can usually be deduced by the extremely sharp edges of the individual elements with no sign of fallout from them, and when they are near the sun, a corona or irisation (also called 'iridescence') is

Figure 10 Altostratus lenticularis.

Figure 11 Altostratus translucidus.

produced due to the diffraction of sunlight by the cloud's tiny ($<10\text{ }\mu\text{m}$ diameter) droplets.

However, there are many cirrocumulus clouds that do form at low temperatures ($<-30\text{ }^{\circ}\text{C}$) and altitudes where cirrus and

cirrostratus form in the high troposphere (Figure 5). These quickly evolve into fibrous cirriform masses within a few minutes, which destroy the granulated appearance required for the label for a cirrocumulus cloud to be applied (see adjacent

Figure 12 Altostratus opacus. It is not raining but close.

Figure 13 Nimbostratus. It is raining lightly.

regions to the right of the cirrocumulus cloud in [Figure 5](#) where the granulation has been replaced by fibrous elements having miniature fall streaks). Therefore, cirrocumulus clouds that transit from liquid to ice become forms of cirrus clouds.

Middle-Level Clouds

Altostratus, altostratus, and nimbostratus clouds ([Figures 6–13](#), respectively) are considered ‘middle-level’ clouds

Figure 14 Stratocumulus.

Figure 15 Stratus.

because their bases are located between about 2 and 7 km AGL (see discussion concerning the highly variable base of what would be called, nimbostratus clouds, aka, 'rain clouds,' below).

All of these clouds are the product of slow updrafts (centimeters per second) often taking place in the middle troposphere over an area of thousands of square kilometers or more. Gray shading is expected in altostratus and is generally

Figure 16 Cumulus humilis.

present in altocumulus clouds. Nimbostratus clouds by definition are dark gray and the sun's location cannot be detected. It is this property of shading that immediately differentiates these clouds from 'high' clouds, ones that with the single exception of cirrus spissatus, have no shading.

Altostratus and altocumulus are different from one another in the same way that cirrus and cirrostratus clouds are different from cirrocumulus clouds. With altocumulus clouds, droplets predominate and that give them a crisp, sharper-edged look as it does with cirrocumulus. In altostratus clouds, ice crystals and snowflakes dominate or comprise the entire cloud giving it a diffuse, fibrous look.

Altocumulus clouds are distinguished from cirrocumulus because they are generally lower and their cloud elements are several times larger than those in cirrocumulus clouds. For example, the elements of an altocumulus cloud are typically the width of three fingers held skyward from the ground. Too, shading toward the center of the thicker elements is usually present in altocumulus clouds, a property that is not allowed in the classification of cirrocumulus clouds.

Altocumulus clouds are distinguished from stratocumulus because they are higher above ground level than stratocumulus (at least 2 km) and because the individual cloud elements in altocumulus are, or appear to be from the ground, smaller than those in stratocumulus.

In spite of its name, altocumulus clouds (Figures 6 and 7, examples of opacus and translucidus, respectively) are overall rather flat clouds that strongly resemble a higher layer of stratocumulus clouds. An exception to this overall laminar architecture is in those species of altocumulus called castellanus (Figure 8) and floccus (Figure 9). In these forms,

altocumulus clouds resemble miniature, lofted cumulus clouds; they truly are 'altocumulus' in the full sense of the name. These forms also usually occur in rows or patches rather than in widespread layers.

In spite of the gray shading that may be present in altocumulus clouds, they are rarely more than 1 km thick. This gray shading is because the concentrations of drops in them are relatively high (typically 50 to several hundreds of thousands per liter) compared with fibrous ice clouds whose particle concentrations may only be several to a few hundreds per liter and are relatively transparent though usually deeper. The concentration of droplets in altocumulus clouds is usually sufficient to produce an 'optical depth' of 4 or more in which the sun's disk is obscured.

Altocumulus clouds sometimes sport patchy 'virga' (Figure 9). Virga is light precipitation that falls from a cloud but does not reach the ground due to evaporation. Because virga is almost always due to falling snow, it appears fibrous, often with striations or long filaments that often far surpass the depth of the cloud from which it is falling (Figure 9). Altocumulus clouds with virga are predominantly those clouds whose temperatures are lower than -10°C . However, at the same time, they are rarely colder than about -30°C . This is because at very low temperatures, they are likely to take on the attributes of ice clouds such as cirrus or its thicker icy brethren, altostratus and as such would no longer be classified as altocumulus.

The species of altocumulus clouds called altocumulus castellanus and floccus (Figures 8 and 9) have always had a special significance in meteorology because these clouds reveal a 'conditionally' unstable lapse rate in the middle

Figure 17 Cumulus humilis shedding ice (areas of where a thin veil-like cloud is present). These clouds are almost certainly colder than -15°C .

troposphere. Conditional instability has been viewed as an indicator for likely releases of deeper convection in the hours ahead such as in thundery weather. Occasionally, altocumulus castellanus clouds themselves group and deepen upward into high-based cumulus and cumulonimbus clouds with significant rain.

When the winds are relatively strong aloft (greater than about 20 m s^{-1}) and moderately moist, but stable lapse rate conditions are present, a species of altocumulus called 'lenticularis' (lens or almond shaped) clouds may form over or downwind of mountains (Figure 10). Altocumulus lenticularis clouds can hover over the same location for minutes to hours while expanding and shrinking in response to fluctuations in the relative humidity of the air mass being lifted over the terrain. Because the conditions under which these clouds form are most often associated with advancing short wave troughs in the middle and upper atmosphere and their accompanying regions of low pressure, lenticularis clouds are usually precursors to deteriorating weather.

With altostratus clouds (Figures 11 and 12), the dominance of ice causes a diffuse, amorphous gray, dull appearance with striations or falls streaks (virga) at the bottom. What an observer

at the ground is viewing at the bottom of altostratus are relatively low concentrations of ice crystals and snowflakes rather than a 'cloud' per se. Those particles at the bottom are evaporating before reaching the ground.

Altostratus clouds are also thick rarely less than 2 km thick and often have tops at the same heights as cirrus and cirrostratus clouds. Because of this great altitude range, they are considerably colder and span a much greater temperature range than do altocumulus clouds. By definition, they cover the entire sky or at least wide portions of it; they are not patchy clouds!

Precipitation is usually imminent when altostratus clouds are moving in because they are a sign that a widespread slab of air, several kilometers deep is rising above you, usually that due to an approaching cyclone and its frontal system. An exception to this rule is in desert regions where the altostratus may be the only cloud that passes over even if a low pressure area and a front moves through.

The relatively low concentrations of large particles in some altostratus clouds (often tens per liter) can allow the sun's position to be seen as though looking through 'ground' or 'fogged' glass. That is, the sun's position is apparent, but the outline of its disk is not. The thin variety of altostratus is termed

Figure 18 Cumulus mediocris.

Figure 19 Cumulus congestus.

altostratus translucidus (Figure 11). In spite of being able to see where the sun is, they are rarely less than 2 or more kilometers thick. Figure 12 shows altostratus opacus, dense, and dull clouds announcing that rain is on the doorstep.

Altostratus translucidus to opacus is a normal progression prior to the onset of precipitation.

When the tops of an altostratus clouds are warmer than about -30°C , the top is, surprisingly, often composed of

Figure 20 Cumulonimbus calvus.

Figure 21 Cumulonimbus capillatus.

a thin droplet cloud virtually identical to an altocumulus cloud layer, but one that produces the initial ice that is found below it. The growth, aggregation, and fragmentation of ice crystals spawned by the topmost liquid clouds over a great

depth usually prevent ground observers from detecting the altocumulus-like cloud at the top. These kinds of situations were dubbed 'the upside-down storm' when first noticed in the mid-1950s because the coldest part of the cloud (the top)

Figure 22 Cumulonimbus capillatus, but one that is entirely above freezing in temperature but exhibits a fibrous structure similar to ‘cold-topped’ cumulonimbus capillatus clouds.

was liquid and the warmer regions below were comprised of ice.

Optical phenomena seen from the ground with altostratus clouds are limited to parhelia (‘sun dogs’ or ‘mock suns’). These are only observed in the variety, altostratus translucidus and normally when the sun is low in the sky. Parhelia are bright, colored highlights that sometimes rival the brightness of the sun that are located 22° from the sun’s position.

Since the composition of the uppermost regions of the deepest altostratus clouds are virtually identical to cirriform ice clouds having simpler, smaller ice crystals, haloes are often observed in the uppermost portions of deep altostratus clouds, for example, as an aircraft ascends through it.

Nimbostratus clouds (Figure 13) are virtually identical to altostratus clouds in their composition except that their bases are usually perceived from the ground as lower than in altostratus, the layer from which it has usually derived due to a downward thickening. In addition, steady precipitation is falling from it. Therefore, they often appear somewhat darker than altostratus clouds and, by definition, do not allow the sun to be seen through them. The perceived base of nimbostratus is found in the melting level where snowflakes are melting into raindrops. This apparent

‘base’ of the cloud is because the greater opacity of snow particles gives the impression of a ‘bottom’ or sharp increase in thickness of the cloud. Therefore, the so-called ‘base’ of a nimbostratus cloud might be perceived at ‘midlevels’ on a day when the freezing level is high (>2 km) such as in southern latitudes or the tropics or be perceived as low when the freezing level is low as in northern latitudes in the winter.

Nimbostratus clouds produce relatively steady precipitation that often continues for hours at a time. They are not clouds responsible for passing showers with periods of sun in between. The tops of dark, steadily precipitating nimbostratus clouds can be as shallow as 2–3 km and even be above freezing in temperature or they may reach into the upper regions of the troposphere (to cirriform cloud levels) and be as cold as -80°C . At altitudes above the freezing level, nimbostratus is largely composed of ice crystals and snowflakes, though embedded thin supercooled droplet cloud layers similar to altocumulus clouds are relatively common. Also, similar to altostratus clouds, when the temperature at the top of nimbostratus clouds is higher than about -30 to -35°C , a thin droplet cloud layer may be found in which the ice crystals form and settle out.

Figure 23 Cumulonimbus capillatus incus, the granddaddy of them all.

Figure 24 Rainshaft from a cumulonimbus.

Though it is not present in [Figure 13](#) nimbostratus from which light rain was falling, a broken-to-overcast layer of shallow stratocumulus ([Figure 14](#)) or stratus ([Figure 15](#)) clouds is usually present at the bottom of them. While usually

not precipitating themselves, these lower cloud layers are important in enhancing the amount of rain or snow that falls from nimbostratus clouds. This enhancement occurs because of the collection of cloud drops in those lower clouds by the

Figure 25 Cumulonimbus mammatus.

precipitation that falls through them in the following way: imagine a cup of water being dumped in the top of a stratocumulus cloud ([Figure 14](#)); more than a cup would fall out at the very bottom of that cloud – if you could catch it all! This kind of precipitation increase is especially evident in hilly or mountainous regions compared with flat regions upwind where there may not be lower clouds.

However, even the existence of lower clouds with drops too small to be collected by precipitation can result in more precipitation than areas without any clouds. Why? This is because where there are no lower clouds, the precipitation is likely to be subject to a bit of evaporation, and the drops or snowflakes are then slightly smaller in comparison to those locations where clouds exist and no evaporation occurs while they are falling through the cloud. Again, imagine dropping a cup of water at the top of a small cloud with tiny droplets, droplets too small to be collected. At the very bottom, you could potentially retrieve your exact cup of water since there was no evaporation inside the cloud. In an area devoid of clouds, even though it is raining, dropping that same amount of water over the same depth as before would lead you to collect less than the full cup you started with. Even though the relative humidity be high, it would be that bit less than 100%, the value required to exactly preserve your cup of water. So, where there are lower clouds, the rain is heavier than without them.

Cumulonimbus clouds (see [Convective Clouds](#)) may also be embedded in nimbostratus clouds. The presence of such clouds within nimbostratus is evident by sudden gushes of much heavier rain and sometimes lightning within a context of relatively steady rain.

Low Stratiform Clouds

Stratocumulus and stratus clouds ([Figures 14 and 15](#), respectively) are low-based (below 2 km AGL), shallow ‘stratiform’ clouds. They are almost always less than 1 km thick. They are composed of droplets unless the cloud top is cooler than about -5 to -10 °C in which case ice crystals may form. Stratocumulus clouds ([Figure 14](#)) differ from stratus clouds ([Figure 15](#)) because they have an obvious rather lumpy appearance at cloud base with darker and lighter regions due to embedded weak convection. These changes in shading represent variations in the liquid water content of the clouds, with the darker regions representing higher amounts of liquid water. Also, the bases of stratocumulus clouds tend to be higher and more irregular in height than those of stratus clouds. Stratus clouds present a smoother, lower, more uniform sky than does stratocumulus clouds because the internal convective overturning that produces lighter and darker regions in stratocumulus is nil in these clouds.

Drizzle precipitation (defined as ‘fine,’ less than $500\text{ }\mu\text{m}$ but greater than $100\text{-}\mu\text{m}$ diameter drops that are also close together and nearly float in the air) often falls from these clouds when the cloud droplet concentrations are lower than about 100 cm^{-3} . In these cases, a broad droplet spectrum that is one to where the cloud droplets have reached beyond about $30\text{ }\mu\text{m}$ in diameter are frequently present in the upper portions of such clouds. When cloud droplets attain sizes larger than this, they begin to stick together when they bump into each other, producing a much larger drop, one that can fall out as a drizzle drop. Due to the requirement for ‘clean’ conditions, drizzle is common from both stratus and

stratocumulus clouds in regions with few CCN such as at sea and especially along and slightly inland of western coastlines in periods of onshore flow.

However, recent measurements have also shown that drizzle and light rain can also develop in these shallow clouds in surprisingly far inland locations in which occasionally very clean conditions are observed such as in the interior of the United States in winter. Since these latter clouds are often supercooled in wintertime and affect populated areas with airports, they pose a severe potential for aircraft icing when freezing rain or drizzle forms in them.

Convective Clouds

Cumulus and cumulonimbus clouds (Figures 16–25, respectively) illustrate convective clouds, those clouds brought about when the temperature decreases rather rapidly with increasing height above the ground. Differential heating and converging air currents in this vertical temperature structure can therefore send plumes of warmer air skyward with relative ease since those plumes will likely be warmer than the air around them.

Convective clouds are limited in coverage compared with stratiform clouds and, except for the anvil portions of cumulonimbus clouds, rarely cover the entire sky or do so only for short periods. This coverage characteristic differentiates cumulus clouds, for example, from stratocumulus clouds because the latter have linked cloud bases covering large portions of the sky. Similar-sized cumulus clouds must, by definition be relatively scattered into isolated clouds or small clusters with large sky openings.

Cumulus clouds are roughly divided into species by their depths. For example, cumulus fractus, those first cloud shreds that appear at the top of the convective boundary layer, may be less than 100 m thick. Cumulus humilis (Figure 16), the next larger size, should not be more than 1 km thick and looks more like a fat pancake than a heaped up cloud. Figure 17 shows that in very cold situations, that even cumulus humilis clouds can form ice. Cumulus mediocris clouds (Figure 18) show clouds that are beginning to be humped up and resemble the profiles presented by mountain ranges. They are around 1–2 km thick. The largest cumulus species is cumulus congestus (Figure 19), always more than about 2 km deep to several kilometers deep and generally much taller than they are wide.

The tops of these larger cumulus clouds, mediocris and congestus, are marked by sprouting subelements referred to as turrets that appear as noticeable protuberances at the top. Turrets are also crenelated on their surface with dozens of lesser, tuft-like ‘units’ perhaps tens of meters wide. Turrets are generally one to a few kilometers wide. However, in severe thunderstorms, individual turrets may coalesce into groups of many turrets to form a large, tightly packed, and hard-appearing cauliflower mass that roils upward with little turret differentiation.

Cumulus clouds are, with rare exceptions discussed below, composed solely of droplets. They have the highest liquid water concentrations of any clouds in their upper portions where the moist air has been lifted the highest. To be a purely cumulus cloud, very few precipitation-sized particles are in them, though they may be imminent. There is no definite rainshaft,

an appendage requiring the use of the modifier, ‘nimbus,’ Latin for rain.

The development of extensive precipitation in cumulus clouds is one in which a cumulus congestus is also becoming a cumulonimbus cloud and leaving the cumulus category. The depth of this transition is different for different aerosol regimes. In clean conditions, cumulus congestus can migrate to a cumulonimbus having a pronounced rainshaft when they reach depths of only 1.5–3 km thick, such as over the oceans. However, in polluted situations, the depth must be much greater, about 3 km thick over land. The precipitation that falls from cumulonimbus clouds can be either due to collisions with coalescence of cloud drops to form raindrops (a process termed the ‘warm rain process’) or it may be due to the formation of ice particles which then collect water through riming or through the aggregation of many ice crystals into snowflakes that melt on the way down. In the cases where the warm rain process is the sole producer of raindrops, the cumulonimbus clouds are necessarily shallower than those requiring an ice process for a strong rainshaft since their tops will be only around or below the freezing level altitude.

Often times in maritime locations and also for clouds in continental locales with warm bases (above about 10 °C), both processes, the warm rain and the ice process, are active.

In wintertime, even small to moderate cumulus clouds with tops colder than about –10 to –15 °C can produce virga, snow flurries, or even accumulating amounts of snow (Figure 17). These kinds of small, cold-based, and precipitating cumulus clouds are found in wintertime in such locations as the Great Lakes of the United States, off the east coasts of the continents, over high mountains or deserts regions.

When significant precipitation develops in cumulus congestus clouds, the visual attributes begin to change noticeably. In the first stage of this change, often very subtle and hard to detect without a practiced eye, the cloud is called a cumulonimbus calvus (‘bald,’ Figure 20). Often, a strong precipitation shaft is seen below cloud base with a cloud top that has softened from a hard, crenelated appearance. In some cases, the rainshaft has not yet appeared or is just emerging, an exciting moment! The ‘soft,’ fibrous, fraying, or wispy transition, sometimes compared to the look of ‘cotton candy,’ is due to the lowering of the concentrations of the particles from 50 to hundreds of thousands per liter of small cloud droplets (<50 µm diameter), to only tens to hundreds per liter of much larger diameter particles that are fractions of a millimeter to greater than millimeter sized. These precipitation particles can be raindrops or ice particles or briefly, both. These larger particles tend to fall in filaments and often produce a striated appearance.

This process from the ‘hard’ to ‘soft’ appearance of a cloud top takes just a few minutes, typically around five or so, that is, to the point that most observers can recognize that ‘something has changed’ at cloud top from the time the cloud was a congestus. If there is already a strong shaft, it is likely that you are viewing the upwind side of a cumulonimbus cloud where new turrets are forming and are going through the complete glaciation cycle and the fibrous appearance which was normally expected to see with fully developed rainshafts is hidden from view and downwind from the observer.

When the fibrousness of the upper portion of the cloud is readily apparent, the cumulonimbus cloud has transitioned from a 'calvus' to a capillatus (Latin, 'hair' – grew 'hair' after being 'bald!'). At this point, when the capillatus stage is reached, all of the upper portion of the cumulonimbus clearly consists of ice crystals and snowflakes (Figure 21). In the tropics or in warm humid air masses, this visual transformation also occurs but can be due solely to the evaporation of the smaller drops leaving the much lower concentrations of drizzle and raindrops that result in a softening of the clouds appearance (Figure 22).

Hail or graupel (small, soft hail) are usually found, if not at the ground, then aloft in virtually all cumulonimbus clouds that reach above the freezing level.

If a pronounced flattening of the top of these clouds develops into a spreading anvil, then the cloud has achieved the status of a cumulonimbus capillatus incus (incus, Latin for 'anvil,' Figure 23). With the familiar anvil, it is perhaps the most recognizable form of a cumulonimbus cloud. The flattening at top usually indicates that the updraft has reached the tropopause, and therefore, these cumulonimbus clouds are more likely than 'capillatus' versions to be severe storms. And watch out if a mound or towering dome of cloud appears above the flattened top! That dome represents an updraft that has overshot the troposphere and entered the stratosphere, the sign of an exceptionally strong updraft within that thunderstorm. So, a dome above the anvil is a very good sign of an especially severe thunderstorm, one that you would not want to drive your car under.

Updrafts may reach tens of meters per second in cumulus and cumulonimbus clouds, particularly in warm air masses. The greatest updraft speed that has been measured by an aircraft was an astounding 40 m s^{-1} ! These strong updrafts lead to large amounts of condensation and liquid water content in the upper regions of these clouds, and often at temperatures far below freezing, even to -30°C !

Depending on how warm cloud base is, the middle and upper developing portions of deep cumulus clouds might contain $1\text{--}5 \text{ g m}^{-3}$ of condensed water in the form of cloud droplets and raindrops. Supercooled water concentrations of these magnitudes are sufficient to cause a buildup of ice on an airframe of about 1 cm or more of for every 1–2 min in cloud. No aircraft can fly for long with such an accumulation of ice and therefore, cumulus and cumulonimbus clouds are avoided by aircraft.

Cumulonimbus clouds are the only clouds that produce lightning. If lightning is observed, the cloud type producing, it is therefore designated as a cumulonimbus. Unlike other clouds, too, the bases of cumulonimbus clouds are marked by strong rainshafts, a feature that differentiates them from nimbostratus clouds. Therefore, when strong rainshafts are observed (Figure 24), the cloud producing, it is also assumed to be a cumulonimbus even if lightning is not observed.

Occasionally, too, large downward projecting protuberances are seen in connection with cumulonimbus clouds. These formations are called 'mammatus,' Figure 25. Contrary to popular opinion, mammatus formations may or may not be associated with a strong thunderstorm. Mammatus are also seen in such tame clouds as altostratus and cirrus.

Cumulonimbus clouds span a wide range of depths, from miniature versions only about 2 km deep in polar air masses over the oceans, ones that never produce lightning, to as much as 20 km in the most severe thunderstorms in equatorial regions, the plains of eastern China, in Brazil and Argentina, and the plains and southeast regions of the United States. However, the most lightning on earth occurs in the interior of central Africa along the Equator.

Synopsis

A cloud climatology describes the time-averaged geographical distribution of cloud properties and their diurnal, seasonal, and interannual variations. Visible and infrared radiation measurements from space are used to obtain cloud top height, cloud optical thickness, and droplet sizes. Visual reports from surface observers on land and sea are used to obtain the frequency of occurrence and the amount of sky covered by each of the various cloud types such as cumulus, stratus, and cirrus. This article summarizes results from both analyses, emphasizing the half-century period of record available from the surface-based climatology.

Introduction

Clouds are an important component of the Earth's climate system. They reflect solar radiation back to space, they absorb thermal infrared radiation emitted from below, and they produce rain and snow. A cloud climatology describes the time-averaged geographical distribution of cloud properties and the diurnal, seasonal, and interannual variations of these properties.

Cloud climatologies are used to determine the radiative effects of clouds on climate and to determine the extent to which interannual and multidecadal changes in the Earth's radiation budget can be attributed to changes in clouds. Cloud climatologies also find applications in assessing the prediction of clouds by climate models, assessing the significance of chemical reactions in clouds, quantifying climatic feedbacks involving clouds, estimating the radiative forcing by anthropogenic aerosols, selecting sites for astronomical observatories and atmospheric field experiments, and assessing the potential for solar energy development.

The properties of clouds most important for climate are those that affect radiation and precipitation, namely cloud height, thickness, horizontal extent and horizontal variability, water content, phase (liquid or ice), and droplet and crystal sizes. It is therefore important to distinguish different types of clouds. The climatic effects of clouds further depend on the geographical location of the clouds, the albedo and temperature of the underlying surface, the season, and the time of day. The effect of clouds on the Earth's radiation budget, called the 'cloud radiative effect,' is generally negative in the daytime but positive at night (i.e., clouds cool the surface in the day but warm the surface at night), so an accurate determination of the diurnal cycle of each cloud type is an important component of a cloud climatology.

Cloud Types

Clouds are classified according to their form and height. Low clouds, with bases in the atmospheric boundary layer less than 2 km above the surface, are influenced by their proximity to the surface. Solar heating of the surface can initiate convection and cause cumulus (Cu) clouds to form at the lifting condensation level. Cu clouds are small and may develop further into large cumulonimbus (Cb) clouds. Cb can extend vertically to the tropopause and often contain ice

crystals in their upper parts. Cb are associated with thunder, lightning, and showery rain or snow.

Stratus (St) and stratocumulus (Sc) are both horizontally extensive low clouds. They are distinguished in that Sc contains convective elements but St does not. Fog is a cloud at the ground surface, usually in the form of Sc. St and Sc cover large regions of the oceans. In the subtropics, they are found over the eastern parts of the oceans, where subsidence is occurring in the free atmosphere above the boundary layer.

Nimbostratus (Ns) clouds are much thicker than Sc and St, extending vertically through several kilometers of the atmosphere. Ns clouds form as a result of large-scale uplift of moist air near frontal boundaries in synoptic-scale storms at middle and high latitudes, and they precipitate rain and snow.

Clouds with bases 2–6 km above the surface are termed 'middle' clouds, and are classified as altostratus (As) or altocumulus (Ac) by their resemblance to St or Cu. Clouds with bases between 6 km and the tropopause are the 'high' clouds: cirrus (Ci), cirrostratus (Cs), and cirrocumulus (Cc). They consist of ice crystals and as a group are called 'cirriform' clouds. They can result from gradual uplift in large-scale storms in midlatitudes, or can be sheared off the tops of Cb in the tropics.

Clouds above the tropopause are rare, but they can occur in the polar regions in the stratosphere at 15–25 km height as polar stratospheric clouds (PSCs; nacreous clouds), and in the mesosphere at 80 km height as polar mesospheric clouds (PMCs; noctilucent clouds). These two types of clouds are discussed in other articles in the encyclopedia; this article is concerned only with tropospheric clouds.

Satellite Observations

Cloud climatologies have been developed from two kinds of data: (1) using radiances measured by satellites in polar and geostationary orbits; and (2) using visual observations of clouds from the Earth's surface, as coded in weather reports from stations on land and ships in the ocean. Satellites detect clouds principally at visible and thermal infrared wavelengths. At visible wavelengths, cloudy scenes appear brighter than cloud-free scenes when viewed from above. Clouds are usually colder than the underlying surface, so the emission of thermal infrared radiation to space is less than for clear scenes. During the daytime clouds can be detected in both wavelength regions, but at night only in the thermal infrared. The altitude of the cloud

top is inferred by relating the infrared emission temperature to the vertical profile of temperature obtained from radiosondes (carried by weather balloons) or satellite sounders. Cloud optical thickness (opacity) is inferred from reflectance in the visible channel. If a second solar channel (in the near infrared) is available, then the vertically integrated liquid water content, and the effective radius of the droplets, can also be inferred.

Measurements from satellites can be used to produce a cloud climatology if the following criteria are satisfied: (1) pixel size is at most a few kilometers, (2) temporal sampling is conducted at regular intervals throughout the day and night, (3) the coverage is global, and (4) a long period of record (many years) is maintained. To satisfy these requirements, the International Satellite Cloud Climatology Project (ISCCP) uses five geostationary satellites that hover over the equator at five longitudinal locations, and two polar-orbiting satellites. That project began in 1983 and is still continuing.

More detailed information about clouds can be obtained from satellite instruments with finer spatial resolution (e.g., Landsat) and from satellites with more spectral channels (e.g., the Moderate Resolution Imaging Spectroradiometer (MODIS) on the Earth Observing Satellites (EOS)). Three-dimensional information about clouds can be obtained from satellites that look at the same scene from different angles (e.g., the Multi-angle Imaging Spectroradiometer (MISR)). Cloud climatologies are also being developed using satellite-borne radar (CloudSat) and lidar (Cloud Aerosol Lidar with Orthogonal Polarization (CALIOP), Cloud Aerosol Lidar and Infrared Pathfinder Satellite Observations (CALIPSO)). These instruments are useful for studying cloud properties but do not yet offer sufficiently long periods of record to produce a climatology (see **Satellites and Satellite Remote Sensing: Remote Sensing: Cloud Properties**). The principal satellite cloud climatology in use now is therefore that of ISCCP.

Surface Observations

The surface observations of clouds are made less frequently than satellite observations in many areas, and they have variable spatial density, but they offer a useful adjunct to satellite observations for the following reasons.

1. The surface observer views clouds from below, and thus can observe the low clouds, which are often hidden from the satellite's view by higher clouds. Multiple cloud layers often occur together, so the views from above and below are complementary.
2. Some clouds are difficult to detect from satellites (clouds over snow, low clouds at night), because they provide little contrast in albedo or temperature to the underlying surface.
3. The surface observers are close to the clouds, so they can identify clouds by type, including clouds smaller than a satellite's pixel size, which is typically at least 1 km.
4. The cloud types defined morphologically by surface observers are directly related to meteorology and cloud processes, whereas the satellite climatology defines cloud types by their radiative properties.
5. Weather reports of clouds are available for several decades with no change in official observing instructions, so inter-decadal variations and trends can be studied.

This article emphasizes the climatology obtained from surface observations, because that is the subject of the authors' own research.

Cloud Information in Surface Weather Reports

Cloud observations are coded into weather reports using the 'synoptic code' of the World Meteorological Organization (WMO). In some countries, the observations are reported both in the synoptic code and in another code used locally. Reports in these other codes have been used to develop climatologies in some individual countries, but the synoptic code is the only one used worldwide. The information about clouds in the synoptic weather report consists of total cloud cover, low or middle cloud amount, low cloud type, middle cloud type, high cloud type, present weather, and base height of the lowest cloud.

About 6500 land stations routinely report cloud observations in the synoptic code. Usually, they report every 3 h beginning at 00.00 coordinated universal time (UTC), but about one-quarter of them report only every 6 h. About 20% of the stations do not make observations at night. The average spacing of land stations is about 180 km, but it is far from uniform. Europe has more stations than needed for a cloud climatology, and Antarctica has too few. Some parts of the Sahara Desert and Western Australia are also inadequately sampled.

Most ships make weather observations four times per day; the observations are recorded in logbooks and also transmitted by radio to world meteorological centers. In a recent typical year, reports from an average of 1150 ships were received at 00.00, 06.00, 12.00, 18.00 UTC and from 160 ships at 03.00, 09.00, 15.00, 21.00 UTC. Most of these are merchant ships with volunteer weather observers; some are military ships and research ships, and a few (less than 10) are dedicated weather ships. Unlike on land, there is little tendency for fewer observations at night, but the nighttime observations may not be transmitted promptly by radio, so it is important to have the complete logbook records. The average spacing of ships that report clouds is 600 km, much greater than for weather stations on land, but the ships are moving so they do sample most parts of the ocean. A project to compile ship-based weather observations from all maritime nations, including many logbook reports, has resulted in the International Comprehensive Ocean-Atmosphere Data Set (ICOADS), which is being used for research on air-sea interaction and climatic change throughout the world ocean.

In many parts of the ocean, the accuracy of computed mean cloud amounts is limited by the scarcity of observations. This is not the case on land, where the random error due to inadequate temporal sampling is very small. Statistical tests performed on observations from weather ships indicate that 100 observations taken at random times during a 3-month period will represent the seasonal mean cloud cover to within 3% in an oceanic grid box of size 5° latitude by 5° longitude. If 1% accuracy is desired, then 1000 observations are needed.

The synoptic code was defined in 1929, but changed in 1949; the reporting procedures became adopted worldwide in the early 1950s. Synoptic observations are available with global coverage for all oceans since 1954 and for all continents since 1971, about 550 million observations to date.

Computation of Average Cloud Amounts

For low clouds, the computation of average amount is straightforward, but for middle and high clouds the question of overlap must be considered. The 'amount' of a cloud type is defined as the fraction of the sky covered by that type, whether visible or hidden behind another cloud. The time-averaged amount can be obtained as the product of frequency-of-occurrence (fraction of weather observations in which a cloud of this type is present, whether visible or hidden) and amount-when-present (the average fraction of the sky covered by this cloud type when it is present, whether visible or hidden). For example, if Cu is present in 30% of the weather observations from a station, and if it covers on average 40% of the sky when it is present, then the average amount of Cu at that station is 12%.

The amount, or even the presence, of a middle or high cloud may be indeterminate when a lower cloud nearly or completely covers the sky. The average amounts of middle and high cloud types can be estimated by assuming that the frequency and amount-when-present are the same in observations where they cannot be calculated and as in observations where they can be calculated. Also, to obtain amount-when-present the clouds at different levels are assumed to be randomly overlapped. The amounts directly visible from below (the 'nonoverlapped' amounts) may also be calculated.

For the climatology, the Earth is divided into an array of boxes on a geographical grid, and cloud cover is computed for each box. There are several possible biases which may affect computed cloud cover but which may be reduced or eliminated with appropriate analysis procedures. Two small biases that oppose each other and are unique to ship observations are the fair-weather bias (the tendency for more ships to enter a grid box on days of fair weather) and the foul-weather bias (the tendency of ships to oversample stormy or foggy weather because they are traveling more slowly). Two other biases that may affect both ship and land data are the diurnal sampling bias (somewhat more reports are transmitted by ships during the daytime than at night, and some land stations in a box with several stations may not report at night) and the trend bias (a box may be sampled by more ships in later years than in earlier years, or a land station may change location during the period of record). These situations can cause biases if the cloud amount undergoes a diurnal cycle or exhibits a long-term trend, but such biases can be eliminated by appropriate analysis procedures.

The most serious bias, on both land and ocean, is the 'night-detection bias.' Visual observations of clouds are hindered at night due to inadequate illumination of the clouds. This usually leads to an underestimation of the average cloud cover at night, especially for the amounts of middle and high clouds, in climatologies based on surface observations. The diurnal cycles of cloud amounts, if based on all the surface observations, are therefore in error, but the cycles can be obtained more accurately if the nighttime observations are screened to select those made under sufficient moonlight or twilight. A criterion for adequacy of moonlight or twilight has been established; it permits the use of about 38% of the nighttime observations. By this criterion, adequate illumination is provided by a full moon at an elevation angle of 6° or a partial moon at higher elevation, or twilight from the sun less than 9° below the horizon.

A complete description of the climatology of clouds is the subject of atlases such as those in the bibliography, which give the average amounts of each cloud type for each season in grid boxes of 5° latitude by 5° longitude, as well as their diurnal cycles and interannual variations. A few illustrative examples from the climatology are shown in this article. Updated plots and descriptions are available at the climatology website: www.atmos.washington.edu/CloudMap.

Global Averages

The annual average total cloud cover as determined from surface observations is summarized in Table 1. Average cloud cover is greater over the ocean than over land. Cloud cover over land tends to be greater in daytime than at night, but the ocean shows little day-night difference.

Cloud properties from 8 years (1986–93) of the ISCCP are summarized in Table 2. The average cloud cover and the day-night differences are slightly different than those obtained from surface observations (Table 1). The optical thickness (opacity) and cloud water path (vertically integrated liquid water content) inferred from the satellite radiances are smaller than those usually obtained from aircraft in field experiments. This difference is probably due to horizontal inhomogeneity of the clouds; ISCCP's optical thickness is an effective optical thickness for a hypothetical horizontally homogeneous cloud.

Global average amounts for nine different cloud types defined in the surface observations are shown in Table 3. Globally, the most common types are Sc, Ac, and high (cirriform) clouds. All the low cloud types are more common over the ocean than over land. The middle cloud types As and Ac together cover the same fraction of the sky over land as over ocean; cirriform cloud is the only type that is less common over ocean.

For the low clouds, Table 3 also shows the observers' estimate of the height of the cloud base above the ground surface. The bases are on average twice as high over land as over ocean, and the heights increase with distance inland from the ocean.

Table 1 Annual average cloud cover from surface observations (1971–96, land; 1954–97, ocean)

	<i>Land</i>	<i>Ocean</i>	<i>Globe</i>
Average total cloud amount (%)	54	69	64
Day–night difference (%)	4	–1	0

Table 2 Annual average cloud properties from the ISCCP (1986–93)

	<i>Land</i>	<i>Ocean</i>	<i>Globe</i>
Average total cloud amount (%)	58	72	68
Day–night difference (%)	+5	–2	0
Cloud top temperature (°C)	–20	–7	–11
Day–night difference (K)	+12	+2	+5
Cloud top pressure (mbar)	490	620	580
Cloud optical thickness	4	4	4
Cloud water path (g m ^{–2})	76	61	66

Data from Rossow, W.B., Schiffer, R.A., 1999. Advances in understanding clouds from ISCCP. Bulletin of the American Meteorological Society 80, 2261–2287, Boston, MA: American Meteorological Society.

Table 3 Cloud type amounts and heights from surface observations

Cloud type	Annual average amount (%)		Base height (meters above surface)	
	Land	Ocean	Land	Ocean
Fog	1	1	0	0
St	5	13	500	400
Sc	12	22	1000	600
Cu	5	13	1100	600
Cb	4	6	1000	500
Ns	5	5		
As	4	6		
Ac	17	18		
High (cirriform)	22	12		
Clear sky (frequency)	22	3		

Land values for the years 1971–96. Ocean values are for the years 1954–2008, from Table 9 from: www.atmos.washington.edu/CloudMap/Atlases/DistOcean.pdf. The amounts of all the cloud types add up to more than the total cloud cover because of overlap.

Geographical Variations

What the averages of **Table 3** cannot show is that there are striking geographical variations. Fog is rare over most of the globe but its frequency exceeds 10% over the North Atlantic and North Pacific oceans in summer poleward of 40° N, and reaches 20–40% in the Sea of Okhotsk. Ns is likewise rare in the tropics but common in middle and high latitudes. Cb amount exceeds 10% in a narrow band along the intertropical convergence zone (ITCZ) near the equator and over a much broader region of warm water in the Western Pacific called the ‘warm pool.’

Completely clear sky, also given in **Table 3**, is common over land but rare over the ocean. Over most of the open ocean there

are almost always some low clouds visible from ships; the reports of clear sky are mostly confined to coastal regions. The Red, Mediterranean, and Arabian Seas are the most cloud-free parts of the world ocean.

The geographical distribution of total cloud cover for Dec.–Jan.–Feb. (DJF) is shown in **Figure 1**. This is the only season in which complete global coverage is available from surface observations, because ships avoid the Antarctic Ocean in other seasons when it is ice-covered. The largest cloud amounts are found in the high latitude oceans, particularly in summer, exceeding 90% in the sub-Antarctic in DJF. The North Atlantic and North Pacific cloud amounts reach similarly high values during the northern summer (Jun.–Jul.–Aug. (JJA)). Values of cloud cover below 40% are found in the deserts of Australia, Central Asia, Arabia, North Africa, Southern Africa, and Mexico. Most of the Indian subcontinent has cloud cover 20–30% on this map, during the winter monsoon dry season. The Eastern Sahara is the clearest large region on the Earth, with cloud cover below 20% on this map for DJF, but it is even clearer in summer when a large area of less than 5% cloud cover extends on across Northern Arabia. A complete set of maps (for all types in all seasons) is available at the website: www.atmos.washington.edu/CloudMap.

The ITCZ appears in **Figure 1** as a latitudinal maximum near the equator in the Atlantic and north of the equator in the Eastern Pacific, then south of the equator through Indonesia, and at about 10° S across the Indian Ocean, Africa, and South America. This is in agreement with the location of the ITCZ as determined by measurement of winds and pressure.

The total cloud cover averaged around latitude zones is shown in **Figure 2** for the two extreme seasons. The figure shows that the average cloud cover is less over land than over ocean, and that the latitudinal variation of cloud cover is greater over

Figure 1 Percent total cloud cover for DJF from surface observations (weather stations on land, ships in the ocean) for the 26-year period 1971–96 over land and the 44-year period 1954–97 over the ocean.

land than over ocean. The peak cloudiness in the ITCZ moves from 7° N in JJA only to 2° N in DJF over the ocean, but to as far as 12° S over land. The latitudes of maximum cloud cover near 60° N, 60° S, and the equator correspond to the latitudes of maximum precipitation, and the latitudes of minimum cloud cover on land are the latitudes of the great deserts.

Diurnal Variations

The amounts of many cloud types vary from day to night. Two examples of diurnal variations for oceanic regions are shown in Figure 3. The central North Pacific in winter exhibits no diurnal variation, with total cloud cover averaging about 82% at all hours. The largest oceanic diurnal variations are in the Sc regions of the eastern subtropical Atlantic and Pacific. The region displayed, in the Atlantic Ocean west of Namibia, exhibits a strong diurnal cycle in total cloud cover with a peak of 80% at 04.00 and minimum of 55% at 16.00. This cycle is paralleled by the diurnal cycle of low stratiform clouds, indicating that these cloud types are the types responsible for the diurnal cycle here. These boundary layer clouds develop during the night and dissipate during the day under the influence of solar heating.

Figure 4 shows an example of diurnal cycles on land, in Central America during the summer rainy season. Solar heating of the surface begins at sunrise, leading to convection which produces Cu clouds in the morning. In the afternoon, many of these clouds further develop into Cb, which continue precipitating into the evening.

Figure 2 Zonal average total cloud cover (average of day and night) for 5° latitude zones. Separate averages are formed for the land and ocean parts of each zone. (a) DJF and (b) JJA. Data span the periods 1971–96 over land, and 1954–97 over the ocean.

Figure 3 Diurnal cycles of oceanic cloud, from ship observations in DJF (1954–97). North Pacific: 40–50° N, 170–150° W; Southeast Atlantic: 20–30° S, and 0–20° E.

Seasonal Variations

The largest seasonal variations of cloud cover are associated with the subtropical monsoons of Africa, South America, India, and Australia. Cloud variations in the Indian Ocean region are shown in Figure 5(a). In Southwest India, the average total cloud cover increases from 16% in February to 89% in July. During India's dry winter, Northern Australia experiences its cloudy and rainy summer.

In contrast to the sinusoidal pattern of the Indian and Australian monsoons, the Central Arctic Ocean (Figure 5(b)) exhibits a peculiar boxlike seasonal cycle, in which cloud cover increases rapidly during May. The greater cloud cover from June

Figure 4 Diurnal cycles of Cu and Cb amounts reported from weather stations in Central America (10–15° N, 85–90° W) in summer (JJA 1971–96).

Figure 5 Examples of seasonal cycles of total cloud cover from surface observations. (a) Land (1971–96): Southwest India, 15–20° N, 70–75° E; Northern Australia, 10–15° S, 130–135° E. (b) Ocean (1954–97): North Atlantic, 40–50° N, 20–30° W; Arctic Ocean, 80–90° N. Observations in the Arctic Ocean were made from drifting stations established on perennial sea ice.

to September is due mainly to the low thin 'Arctic summer St' clouds that form over the perennial sea ice during the melting season. A still different pattern is exhibited in parts of the North Atlantic (Figure 5(b)) which have almost no seasonal variation of cloud cover.

Figure 6 shows a map of the amplitude of the seasonal cycle of total cloud cover over both land and ocean. With the exception of the North Atlantic, the regions shown in Figure 5 appear in Figure 6 as darker areas, indicating a large amplitude. Other areas showing a large seasonal cycle include tropical South America, Central America, the Sahel, and Southern Africa. This figure also illustrates the tendency for ocean areas to have a less pronounced seasonal cycle than land areas.

Interannual Variations and Trends

Clouds interact with other components of the climate system, so changes in cloud amounts can be expected to accompany changes in other climatic variables, and also to feed back on those other variables. The magnitudes, and even the nature, of the possible climatic feedbacks involving clouds are not well understood, but the long historical climatic record may help to identify them. The degree to which the actual variations of the amounts of the different cloud types are faithfully recorded in the analysis of visual observations is itself variable, depending on the spatial and temporal density of observations, the ability to detect and remove biases, and the spatial scale of the analysis. Real interannual variations of cloud amount in a $10^\circ \times 10^\circ$ grid box, for example, are often large enough to overwhelm any subtle progressive changes in observing procedure. However, interannual variations of zonal average cloud amount are smaller than

Figure 6 Amplitude (percent) of the seasonal cycle of total cloud cover over land (1971–96) and ocean (1954–97).

those of grid box cloud amount because of partially compensating positive and negative changes in different parts of the zone. For zonal averages, it is therefore more difficult to dissect the observed changes into climatic and nonclimatic causes.

A powerful way to assess the validity of observed cloud changes is to identify likely causes (e.g., changes in sea surface temperature (SST) or atmospheric circulation) and effects (e.g., diurnal temperature range) of the cloud changes and to correlate these related climatic variables with the cloud changes. Some examples are shown in Figure 7. Interannual variations of the amount of marine stratiform cloudiness ($St + Sc$) commonly correlate negatively with interannual variations of SST. Figure 7 shows how $St + Sc$ and SST (both measured aboard ships, but by different methods) covary at two locations in the Pacific Ocean. Many of these interannual variations are related to cycles of El Niño and the Southern Oscillation. Frame b shows downward spikes in stratiform cloud cover coinciding with high SST (plotted as increasing downward) during strong El Niño years: 1972–73, 1982–83, and 1997–98. That clouds and SST are measured differently but correlate well argues for the reality of both time series. The strong correlations in Figure 7 also suggest that the error in a seasonal mean due to

random sampling of weather situations during a particular season is small. In other grid boxes traversed by fewer ships, seasonal means suffer from sampling error and the correlation of $St + Sc$ with SST is not as strong.

Cloud cover changes may accompany the global warming brought on by anthropogenic increases in greenhouse gases. Regional changes in cloud cover may also be expected from anthropogenic sulfate aerosols that can act as cloud condensation nuclei. Figure 8 shows trends (0.1%/decade) in total cloud cover for grid boxes from 1971 through 1996. Decreases in total cloud cover are observed over South America, Southern Africa, and in a large area between Southern Australia and Northern China. Decreases in cloud cover are also seen in all eastern subtropical ocean basins. Increasing cloud cover is observed in the Central Equatorial Pacific, Western Africa, and Arctic North America. The causes of these observed changes in cloud cover are still under investigation.

Individual time series for selected boxes (shown in Figure 8) showing significant trends in total cloud cover are plotted in Figure 9. Time series are plotted as seasonal anomalies (the departure from the multiyear seasonal mean cloud cover). Figure 9(a) shows the time series over the Equatorial

Figure 7 Seasonal average daytime amounts of St plus Sc , and seasonal average SST for two grid boxes in the Pacific Ocean. (a) JJA, $30\text{--}40^\circ\text{ N}$, $160\text{--}180^\circ\text{ W}$. (b) JJA $0\text{--}10^\circ\text{ S}$, $80\text{--}100^\circ\text{ W}$. The SST is plotted on a reversed scale to illustrate the correlation. (SST data provided by the Hadley Centre HadISST1 product.)

Figure 8 Yearly average trends (0.1%/decade) in total cloud cover over land and ocean (1971–96). Boxes A, B, and C used in **Figure 9** are labeled.

Figure 9 Time series of anomalies (percent departure from seasonal average) of total cloud cover in the three grid boxes outlined in **Figure 8**: (a) Equatorial Pacific, (b) South America, and (c) Indonesia (using both land and ocean data). Each point represents one year's seasonal anomaly. Trend lines are fit to the time series and shown in red (increasing) or blue (decreasing).

Figure 10 North American weather stations contributing cloud observations to the global climatology in (a) 1985 and (b) 2005.

Pacific. While an increasing trend of about 6% over 26 years can be seen, the year–year variation ranges up to 20% with three distinct spikes, likely associated with El Niño activity. Frames b and c show decreasing cloud cover over boxes in South America and Indonesia, respectively. The year–year variations in these boxes are also greater in magnitude than the trends, which show a decrease of roughly 10% over 26 years. This figure shows that while significant trends in these areas are apparent, the trends are not drastic and it is still normal to see above or below average cloud cover during any given season.

At present, it is difficult to obtain reliable multiyear trends of cloud amounts from satellite observations because of the short lifetime of individual satellites and the difficulty of intercalibrating instruments on different satellites, especially because the spectral response of the radiation detectors may change from one satellite to the next. However, efforts are underway to address these problems, and in the future more use will be made of satellite observations to detect long-term changes of cloud amounts.

The Future of Cloud Observations

The long time span of cloud reports, covering the transition period from a time of perhaps minimal human impact on climate in the 1950s to the anthropogenically altered climate of the future, is a valuable resource that is appreciated by many national meteorological agencies. There has been remarkable worldwide international cooperation in reporting weather

observations in compliance with the WMO regulations. Except for brief periods of political instability (Iran in 1979, Zaire in the late 1990s), essentially all nations have been contributing their weather observations reliably. Recently, however, three nations (United States, Canada, and New Zealand), in conjunction with the automation of their weather stations, have essentially ceased reporting of visual cloud observations in the WMO synoptic code. Changes of codes or changes of observational methods (laser ceilometers in place of the human eye), or even changes of station location, make it difficult to infer reliable climatic changes over a span of years that includes the time of the change. The number of US stations with useful synoptic weather reports decreased slowly throughout the 1980s and rapidly in the mid-1990s, so that the geographical coverage of the US declined from 241 stations in 1981 to only about 27 by the end of 1996. This transition is illustrated in Figure 10, which plots the locations of weather stations reporting visual cloud observations in 1985 and 2005. While Mexico, the Caribbean, Bermuda, Venezuela, remote Eastern Siberia, and Greenland have dutifully continued to report cloud observations, the United States and Canada currently furnish only a handful of reliable weather stations. The United States, Canada, and New Zealand together represent 4% of the Earth's surface, so future global analyses of cloud changes from surface observations will be restricted to the remaining 96% of the globe.

Synopsis

The impact of clouds on weather and climate is determined by their microphysical properties (i.e., the size distribution, water content, optical properties, and shape). Understanding how these properties evolve requires detailed studies with *in situ* measurements using a suite of different sensors. This article gives an overview of the different techniques that are used to determine these cloud characteristics and examples of some of the types of information that can be extracted from these data.

Cloud Properties and Their Impact on the Environment

Climate, weather, and hydrologic cycles are strongly affected by the temporal and spatial properties of clouds. Clouds consist of liquid water or ice hydrometeors whose number concentration, size, density, and shape determine these properties. **Table 1** lists the environmentally important properties of clouds and the hydrometeor characteristics to which they are connected. **Table 2** defines these properties with respect to hydrometeor characteristics and the equations that relate them to the size distributions of cloud particles.

Clouds impact climate primarily by altering the radiative balance in the regions where they form. Hence, cloud particle optical properties (i.e., phase function, extinction coefficient, and effective radius) are the important parameters. Weather is affected by clouds not only because of changes in the radiative balance, but also by precipitation. The formation of precipitation depends on the number concentration, size, density, and shape of cloud particles.

In situ measurements of cloud properties provide detail that cannot be obtained from remote sensors like radars and satellites. This detail is needed to better understand the physical processes that govern the evolution of clouds. *In situ* measurements focus on the evaluation of the hydrometeor

characteristics listed in **Table 2**. Some of these characteristics can be measured directly with currently available instrumentation, while others must be derived from the size distribution that can be measured by some of the sensors discussed in this article.

Measurement Techniques

Table 3 lists the general techniques that are used to measure hydrometeor properties. Hydrometeors are detected using five fundamentally different measurement approaches: impaction, phase change, light scattering from individual particles, light scattering from an ensemble of particles, and hydrometeor imaging. The measurement principles and the more frequently used instruments that utilize these techniques are described in this section.

Hydrometeor Detection by Impaction and Replication

This technique was one of the first approaches for examining the size distribution and concentration of hydrometeors. It has been implemented in several ways, but the basic principle is that a small impaction surface in the shape of a cylinder, disk, tape, or wire is exposed to hydrometeors in a moving air

Table 1 Cloud properties, hydrometeor characteristics, and environmental impact

<i>Cloud property</i>	<i>Hydrometeor characteristic</i>	<i>Environmental impact</i>

Chemical-processing efficiency	Number, surface area, and mass concentration Fall velocity	Climate and hydrological cycles

Table 2 Hydrometeor properties

Number concentration (cm^{-3})	$N = \sum_{i=1}^m n_i$
Surface area concentration ($\mu\text{m}^2 \text{cm}^{-3}$)	$S = \pi \sum_{i=1}^m s_i n_i d_i^2$
Mass concentration (g m^{-3})	$M = \frac{\pi}{6} \sum_{i=1}^m s_i \rho_i n_i d_i^3$
Fall velocity (cm s^{-1})	$V_t = f(d_i, g, \rho_a, C_D)$
Phase function	$P_{\lambda, \theta} = \int_{r_1}^{r_2} F(\eta, \lambda, r, \theta) \pi r^2 n(r) dr$
Extinction (m^{-1})	$\sigma_e = \int_{r_1}^{r_2} Q_e(\eta, \lambda, r) \pi r^2 n(r) dr$
Effective radius (μm)	$R_e = \frac{\sum_{i=1}^m n_i d_i^3}{\sum_{i=1}^m n_i d_i^2}$

m = number of size categories.

n_i = number concentration of hydrometeors in size category i .

d_i = average diameter of size category i .

r_i = average radius of size category i .

s_i = shape factor of the hydrometeor of size category i , to account for asphericity (this factor depends upon the intrinsic property being defined).

ρ_i = density of the hydrometeor in size category i .

ρ_a = air density.

g = gravitational acceleration.

C_D = drag coefficient.

F = angular scattering intensity efficiency.

Q_e = extinction efficiency.

η = hydrometeor refractive index.

λ = wavelength of incident light.

θ = angle of light scattered from the hydrometeor.

stream. The surface is coated with a highly viscous liquid to prevent the particles from escaping the surface after impact. The hydrometeors, or their impressions, are subsequently counted and sized with manual or automatic methods to determine the number concentration and size distribution. The version of this technique that is currently in use is the video ice particle sampler (VIPS) that uses a moving, 8 mm transparent tape that is coated with silicone oil and exposed to the particle-laden air stream. After impaction, the captured droplets or crystals are recorded digitally as the tape moves in front of two video cameras. Another similar device, the Cloudscope, uses a video camera to record hydrometeors as they impact a heated glass window. The size of each hydrometeor is deduced from the size and shape of the impacted particle. The rate at which it evaporates provides information on the water mass.

These two instruments are not commercially available but have been developed for research at several institutes. The National Center for Atmospheric Research and the Desert Research Institute (Reno, NV) use the VIPS and Cloudscope in airborne cloud studies, respectively. A dropsonde and balloon-borne instruments (HYVIS), operating on a principle similar to that of the VIPS, have been used by the Meteorological Research Institute in Japan to sample cirrus and thunderstorm clouds for about the last 20 years.

Hydrometeor Mass Detection by Phase Change

Several instruments measure the water content of hydrometeors by measuring the energy of phase change when they

evaporate. Two of these instruments, the hot-wire liquid water sensor and the Nevzorov probe, derive the water mass from the amount of thermal energy required to evaporate the hydrometeors after impaction. This method utilizes a cylindrical or disk-shaped sensor that is maintained at a constant temperature. Thermal energy is removed from the sensor through convection and by the evaporation of water droplets that strike the heated element. The power required to maintain the sensor at a constant temperature is measured, and the thermal energy removed by convection is calculated directly from heat transfer theory so that the remaining energy loss is due to evaporation of water droplets. The water mass, M , that leads to this energy loss is derived from first principles, that is,

$$M = \frac{P - P_d}{AV(L_v + c_w(T_b - T_a))} \quad [1]$$

where

P = measured power;

P_d = convective heat loss;

A = sensor area;

V = air velocity;

L_v = latent heat of vaporization;

c_w = specific heat of water;

T_b = boiling point of water;

T_a = air temperature.

Sensors that utilize a cylindrical geometry are useful only for water clouds since ice crystals will bounce from the heated element before totally evaporating. This characteristic, however, has been utilized in the Nevzorov probe, shown schematically in Figure 1. This instrument uses two heated sensors, one with a cylindrical geometry and the other in the shape of a concave disk. In water clouds, both sensors respond equally. In mixed-phase or total ice clouds, the concave sensor captures the hydrometeors long enough for them to evaporate. Comparison of the total water content from the concave sensor and the liquid water controller (LWC) from the cylindrical sensor provides a measure of the ice water content.

Another method for deriving water mass by evaporation is to measure water vapor that is formed from evaporation of the hydrometeors. The Counterflow Virtual Impactor (CVI) is one common instrument utilizing this technique. At the CVI inlet tip (Figure 2), cloud droplets or ice crystals larger than some minimum aerodynamic diameter (5–10 μm diameter depending on conditions) are separated from the interstitial aerosol and water vapor and ‘virtually’ impacted into dry nitrogen gas or purified air. This separation is possible via a counterflow stream of gas out the CVI tip, which assures that only larger hydrometeors are sampled. The water vapor and nonvolatile, residual nuclei that remain after droplet evaporation are sampled downstream of the inlet with selected instruments. These may include a hygrometer to determine water content, a condensation nucleus counter, an optical particle counter, or in-line particle filters for various chemical analyses. Since droplets or crystals in a large sampling volume converge into a smaller sample stream within the instrument, concentrations within the CVI are significantly enhanced, which leads to more sensitivity.

Table 3 Measurement techniques

Sensing technique	Hydrometeor properties measured or derived	Instruments in active use
Impaction and replication of hydrometeors on a substrate	N : directly M : size distribution integration V_i : size distribution integration $P_{\lambda,\theta}$: size distribution integration R_e : size distribution integration σ_e : size distribution integration	Video ice hydrometeor sampler (VIPS) ^a HYVIS ^b Cloudscope ^c
Phase change of hydrometeors	N : from CVI only M : directly	Hot-wire liquid water sensor ^d Nevzorov probe ^e Counterflow virtual impactor (CVI) ^{a,d,f}

Figure 1 The Nevzorov instrument uses two sensors to determine the liquid water content (LWC) and total water content (TWC). The LWC sensor (a) responds primarily to water droplets, while the TWC (b) responds to water and ice particles.

Hydrometeor Size Detection by Single Hydrometeor Scattering

Optical particle counters detect the light scattered when a particle passes through a focused laser beam. Instruments that convert the light amplitude into a size, using Mie scattering theory, are called single-particle spectrometers. Currently used instruments for measuring cloud droplet sizes and concentrations are the forward scattering spectrometer probe (FSSP), the cloud droplet probe (CDP), the small ice detector (SID), and the cloud and aerosol spectrometer with depolarization (CAS-DPOL). As individual droplets in the free air stream pass through the laser beam and scatter light, the light is collected through a cone with a solid angle from 4° to 12° and a detector converts the photons into an electrical signal proportional to the optical cross-section of the particle. The CAS-DPOL has two additional sets of optics that collect backward-scattered light from 168° to 176° and separate it into two components: one component is measured with a detector behind a polarizing filter, and the second component is measured by a detector with no filter. Comparison of the two components determines if the hydrometeor was an ice crystal or water droplet. **Figure 3** is a diagram of the CAS-DPOL optical configuration showing the primary features of the light-scattering collection system used in optical spectrometers, the main difference being the

Figure 2 Schematic of the CVI inlet. Nitrogen gas is pumped into the annular region formed by two concentric tubes joined at the tip. The gas flows in opposing directions after passing through the porous center tube. The counterflow out the inlet tip prevents small interstitial aerosol particles from entering the inlet, while cloud droplets or ice particles have enough inertia to pass through the counterflow region and enter the sample flow. Once sampled, droplets or crystals are evaporated in the heated tip region.

additional backscatter optics in the CAS-DPOL. The signal-processing electronics analyze the maximum amplitude associated with each light-scattering event and categorize this signal into a preassigned size bin such that, over a specified period of time, a frequency histogram is accumulated that is called a size distribution (i.e., a method of presenting the number of particles in different size intervals that were found in a particular cloudy volume of air). When the particle number is divided by the volume sampled, this size distribution is expressed as a number concentration per size interval. Mie theory, combined with calibration using spherical particles of known size and refractive index, is used to convert the scattered light signal into a size. The cloud properties are then derived, as shown in Table 2, by integrating over this size distribution. The combination of forward-scattering and backscattering signals from the CAS-DPOL is used to distinguish droplets from ice crystals. Figure 4 illustrates measurements made in a mixed-phase cloud where the separation between droplets and crystals is clearly seen.

The SID was specifically designed to discriminate ice from water based upon the angular distribution of light

scattered in the forward direction. The SID-3, the most recent version, uses a charged coupled detector array to measure the azimuthal distribution of light scattered over a forward-scattering angle by individual cloud particles passing through the laser beam.

The SID-3 can discriminate supercooled liquid drops from small ice particles, based on their scattering pattern, and estimate the size of the ice particles up to approximately 140 μm . Figure 5 illustrates some of the patterns that are measured by the SID-3 when viewing water droplets and ice crystals.

Single-particle scattering is also used by the LaMP polar nephelometer to directly measure the phase function of hydrometeors. In this instrument, shown schematically in Figure 6, the particles intersect a collimated, high-energy laser beam (1 W, $\lambda = 804 \text{ nm}$) at the focal point of a paraboloidal reflector. The scattered light is reflected onto a circular array of 54 detectors. Each detector senses signals corresponding to a range of scattering angles. From these measurements, a phase function can be derived, as shown in Figure 7, where the phase function of ice crystals in a cirrus cloud is compared with theoretical predictions.

Figure 3 This block diagram shows the general optical layout for components in the CAS. Light that is scattered while particles pass through the CAS laser beam is collected in both the forward and backward directions and measured with photodetectors. The 'masked detector' has aperture that blocks light that is scattered from particles that pass through the laser beam at distances farther from the center of focus than optimum.

Figure 4 Comparison of the depolarization signal divided by the backscattering nonpolarized signal and the depolarization signal divided by the forward-scattering signal, for individual particle measurements, shows that there are two distinct regimes that separate water droplets from ice crystals. These measurements were made in a mixed-phase cloud.

Figure 5 These images are the azimuthal, forward-scattering patterns measured by the SID-3. The top row shows water droplets with different diameters, and the lower rows are ice crystals with various habits and sizes.

Figure 6 The principal components of the LaMP polar nephelometer are shown in this schematic. The particles intersect a collimated high-energy laser beam at the focal point of the paraboloidal reflector. The scattered light is reflected onto a circular array of 54 detectors.

Hydrometeor Mass and Optical Properties by Ensemble Particle Scattering

Light scattering from an ensemble of hydrometeors is the technique used by several instruments that derive LWC, extinction coefficient, and effective radius from their measurements. Light scattered by particles is composed of three components: reflection, refraction, and diffraction. The FSSP and CAS measure light that is primarily reflected and refracted. In contrast, ensemble-scattering instruments measure mostly the diffracted component of scattered light. The instruments

consist of a light source and one or more detectors that measure transmitted or scattered light from the particle field. The particle volume monitor (PVM), shown schematically in [Figure 8](#), illuminates an ensemble of hydrometeors with a collimated laser and focuses the near-forward scattered light onto two detectors that are masked with variable-transmission filters. The filters have been designed to provide transmission functions that are mathematically derived to approximate inversions of the integral equations that relate particle surface area (PSA) or LWC to the flux of light scattered by the ensemble

Figure 7 An example of a phase function constructed from measurements in cirrus clouds, with the LaMP polar nephelometer is shown in this figure. The red curve exhibits the 22° halo peak due to pristine hexagonal-plated ice crystals, as exemplified from CPI images (upper-right panel). The smooth feature (blue curve) is a common observation in cirrus clouds with prevalent irregular-shaped ice particles (see CPI images on the bottom-right panel).

Figure 8 The principal components of the PVM-100 are illustrated in this schematic. Forward-scattered light from an ensemble of particles in the laser beam is measured by the LWC and PSA detectors. These detectors are masked with variable transmissions filters, whose transmission functions are weighted to provide light that is proportional to LWC or PSA, respectively.

of hydrometeors. It has been shown theoretically that the scattered-light flux $F(d)$, measured by the PVM LWC sensor, for an ensemble of hydrometeors of size d , will be proportional to $k_1 d^3$, where k_1 is a scaling constant. This proportionality holds true if the transmission filter consists of annular segments identified by the subscript j , and $F(d) = \sum_{j=1}^N f_j T_j$, where $f_j(d)$ is the flux of diffracted light incident on j , T_j is the transmission of filter j , and N is the total number of annuli. The transmission functions T_j are determined by mathematical inversion of this relationship, and the scaling factor k is determined through calibrations in a well-characterized wet wind tunnel. A similar procedure is followed to measure PSA as a function of $k_2 d^2$, and different sets of annular filters are used on the PSA detector. The ratio of the PVM LWC to PSA gives a measure of the effective radius r_e (Table 2).

The phase function of hydrometeors, as discussed in Section [Hydrometeor Size Detection by Single Hydrometeor Scattering](#),

can be measured for single particles using an array of detectors. An approximation to the phase function at a given wavelength λ is the asymmetry factor g_λ :

$$g_\lambda = \frac{\int \cos \theta P(\lambda, \theta) d(\cos \theta)}{\int P(\lambda, \theta) d(\cos \theta)} \quad [2]$$

The asymmetry factor is the average cosine of the angles for scattered radiation and provides a measure of the relative amount of forward- and backscattered light from an ensemble of hydrometeors. In other words, this factor is >0 when more light is forward scattered than backscattered, 0 for isotropic scattering, and <0 when the majority of light is backscattered.

One instrument that has been specifically designed to measure g_λ is the cloud integrating nephelometer (CIN). The CIN consists of a collimated laser beam that passes through an ensemble of hydrometeors and four detectors that are positioned to measure scattered light in the forward direction

Figure 9 The CIN, whose primary optical components are illustrated in this schematic, measures an approximation to the total scattering coefficient by adding the scattered light measured by detectors B and F. The cosine masks on detectors cB and cF provide an approximation to the asymmetry factor when divided by the scattering coefficient.

(S1 and S3) and in the backward direction (S2 and S4), as shown in Figure 9. The denominator in eqn [2] is proportional to the total scattering coefficient, and the sum of detectors B and F is an approximation to this coefficient. The cB and cF detectors have optical masks that cosine-weight the scattered light collected by these detectors, and their sum is an approximation to the numerator of eqn [2]. After suitable corrections for the angles over which light is not being collected, the ratio of (cB + cF) to (B + F) provides an approximation to the asymmetry factor.

Nonintrusive Optical Imaging

One of the first methods in cloud physics research for optically measuring hydrometeor size was by imaging onto a linear diode array the shadow of a particle that passed through a laser beam (Figure 10). The on-off state of the diodes in the array is recorded at a rate proportional to the velocity of the particles passing through the laser, and the images can be subsequently reconstructed to show the features of the hydrometeors, as shown in Figure 11. These types of instruments, called two-dimensional optical array probes (2D-OAPs), can typically measure in the size ranges of 10–1280 μm (2D-S probe), 12.5–800 μm (cloud-imaging probe, or CIP), 25–800 μm (2D cloud probe, or 2DC), 100–6400 μm (precipitation imaging probe, or PIP), and 200–6400 μm (2D precipitation probe, or 2DP).

This technique has been refined to measure hydrometeors at a higher resolution (measuring ones as small as 2.5 μm) with the cloud particle imager (CPI), by using a pulsed laser and a two-dimensional photodetector array to capture the particle image. In addition, 256 Gy levels are measured in the CPI. Figure 12 shows examples of some of the ice crystals that have been measured with the CPI.

Holography, another technique for viewing ensembles of cloud particles, provides the position in three-dimensional

Figure 11 This figure illustrates the reconstructed images recorded with a CIP OAP and shows the structure of ice crystals measured at different temperature levels in clouds.

(3D) space, the shape, and the size of each particle in a dilute collection of cloud droplets and ice particles inside a localized 3D sample volume. Simply stated, an in-line hologram is an interference pattern resulting from the superposition of an incident plane wave (the reference wave) and light scattered by the dilute suspension of illuminated particles. The interference of the reference and object waves are called the real and virtual images, respectively. When the real image is reconstructed, the virtual image reconstructs as a blurry background appearing around the reconstructed 'focused' real image. In practice, images of sampled particles are obtained by numerical reconstruction of the recorded digital holograms. Figure 13 shows several reconstructed images of ice crystals.

Figure 10 OAPs measure the shadow image of particles that pass through a collimated laser, as shown in this schematic. The laser illuminates a linear array of diodes whose 'on' and 'off' states are monitored by signal-processing electronics to determine when a shadow is present or not. A two-dimensional image is reconstructed by recording the on and off state of these diodes as a function of time.

Figure 12 These images are examples of the type of measurements that can be made with the CPI. They are representative of the nonpristine, asymmetric crystals that are more often than not seen in clouds and demonstrate the power of the CPI to resolve the very fine structure of small ice crystals.

Figure 13 These are holographic images of small ice crystals.

Synopsis

Fog occurs around the world and leads to many impacts on human and related systems. The formation of fog, its intensity, duration, and coverage are governed by synoptic and mesoscale forces, thermodynamics, and circulations. However, these are modified according to the local physiographic features in a region and vary with atmospheric chemistry and cloud microphysical processes. While the prediction of fog remains difficult due to its significant spatio-temporal variations, advances have been made through numerical modeling. Other uses and impacts of fog have increased with our understanding of the phenomenon and the parameters that determine fog characteristics and behaviors.

Fog as a Phenomenon

The occurrence of fog may lead to a multitude of impacts for a wide variety of activities around the world. These include personal inconvenience and simple annoyance due to delays (e.g., transportation) as well as more serious hazards such as air quality and local visibility. Sometimes these have deadly consequences as well as significant economic effects leading to delays, higher delivery costs, and spoilage of products and goods (e.g., a fog-bound ship near a port of call). While negative consequences are most often associated with fog, several positive benefits exist, including fog harvesting for local agricultural use and water supply. Fog has also been exploited from intelligence and military perspectives and ‘used’ in theatrical and similar productions and performances.

The complexity of fog impacts relates to its character as evident in the atmosphere: while fog may be associated with cleansing of the air it may also enhance contamination of the air by allowing chemicals and aerosols present to be retained. Fog consists of suspended droplets, often of similar size, near or at the ground, some of which may be settling out, scavenged, and/or evaporating, and restricts visibility and persists for a period of time. Fog droplets are characteristically larger than cloud droplets and have diameters near those of drizzle. The droplets are liquid in form and may also consist of supercooled droplets. Fog is often measured according to its restriction to visibility (intensity), its depth (either of the fog layer or the fog ‘top’ relative to the ground surface), and the areal coverage. A great degree of variability in fog’s composition and character is common, even on the smallest of microscales (Table 1).

Although the duration of fog is of importance, there is no standard operational measure or comparative observation. Fog is often labeled by ‘type,’ which is typically based upon its formation process and/or maintenance mechanisms (e.g., radiative, upslope) and on occasion, its location or source (i.e., sea fog, valley fog, etc.). Many types derive from a combination of direct and indirect causes. The origin of the word fog is thought to be primarily from high latitude northern countries and was a term used to describe small/fine rain, sometimes with wind, obscuring visibility. The word is taken from the Greek (nephele) or Latin (nebula) for cloud.

Fog Impacts

World Meteorological Organization Meteorological Terminal Aviation Routine Weather Report (WMO METAR) observational criteria distinguish fog from haze based on visibility considerations, relative humidity, and content. Haze and fog may occur together and have nearly equivalent impacts, but in fog, restriction of visibility predominates. The prevailing conventions define fog by its ‘thickness’ (or ‘intensity’) according to the restriction of horizontal visibility (and sometimes slant range in aviation). Dense, moderate, and light fogs produce visibilities of less than 1 km, 1 to less than 5 km, and 5 to less than 11 km, respectively. These definitions rely on sight distance as a surrogate for measurement of droplet distributions and are exclusive of the occurrence of low stratus clouds. Various designs of transmissometers are used to measure restrictions to visibility; particularly those that limit sight to less than 1 km (Figure 1).

Reductions in visibility are a function of the droplet sizes present and their type, the relative proportion or distribution of

Figure 1 Fog may occur in a wide variety of settings with multiple impacts. Reduced or obstructed visibility is typically the most significant impact of fog. The obstruction is dependent upon the drop-size distribution present as well as the concentration of drops and liquid water content. Impacts vary according to application such as runway visibility for aircraft operations. Pictures: <http://www.publicdomainpictures.net/view-image.php?image=7588&picture=docked-boats&large=1#large>; <http://www.publicdomainpictures.net/view-image.php?image=8903&picture=fog&large=1#large>; Schematic images: prepared by Braden Ward.

these, and their concentrations. It is a combination of fog ingredients, processes, and their interaction with characteristics of the local region that modify the physical chemistry (and sometimes the physical behavior of fog) in the local environment, thus leading to impacts. These are acted upon by radiative and advective processes within the planetary boundary layer from the micro to meso to synoptic scale. Together these create an intricate mix of cloud chemistry that is governed by cloud microphysical constraints and thermodynamic pathways. Given the large variation in scales involved, fluxes and interaction between scales (particularly within the roughness and surface layers of the boundary layer), and the ever-present temporal and spatial changes in a region, the occurrence of fog and its intensity and coverage (including its persistence and duration) will vary widely even when a fairly static, uniform, and homogeneous setting appears to exist in the atmosphere. These frequently lead to varying manifestations of fog in spite of seemingly identical conditions across a region or even at a single location.

While fog impacts on transportation (land, sea, and air travel) are commonly known, those that impact rescue operations,

emergency management, and air quality are less often considered with regard to the fog dynamic and this physical chemistry. Historically several important episodes are noteworthy including the Great Smog of 1952 in London, England, and the 1948 Donora Smog in Donora, Pennsylvania, United States – particularly since these occurred in fog-prone regions. This led to a diminished sense of danger or urgency by the local populations and thus resulted in significant loss of life as well as long-term health effects.

During the Great Smog of 1952, the most common heating method used was of low quality coal, which produces high amounts of sulfur dioxide and particulate matter, which can enhance droplet nucleation processes. The accumulation of these pollutants in the air gave London fogs a characteristic color – and led to the use of the phrase ‘pea soup’ to describe the London fog. The Great Smog lasted 4 days and resulted in many deaths and illnesses. The Donora Smog event of 1948 was similar in terms of duration and pollutant-based hazards. In this case two manufacturing plants of steel, wire, and zinc were responsible for emissions that included hazardous fluorine gas. A persistent temperature inversion in the region

restricted mixing and ventilation of the atmosphere and thus sickened thousands of people and resulted in hundreds of deaths during and after the event.

These two events clearly illustrate the difficulty of an emergency response to widespread respiratory illness within a regional population center. This includes difficulty in counting casualties, implementing emergency evacuations, and responding to the sources and cause in an operational and forecast manner. While the resulting knowledge gained from the Donora Smog and from London experiences led to the creation of more stringent environmental and air quality laws, they did not necessarily provide guidelines for preventive actions and mitigation measures that could be considered. In spite of rapid communications and modeling present today, the prospect of fog episodes creating 'bad air quality events' poses a serious threat to many communities globally whether near an industrial region or not.

In addition, little work has been accomplished in better understanding the impacts of fog on a variety of biological populations (i.e., plants, animals, insects, etc.) or those found in marine and estuary settings. These include fog deposition, surface reaction, and chemical ingestion/reaction. Since fog droplets carry chemical matter, or are found attached to various aerosols in the atmosphere (including those that may be radioactive), the surfaces, which they contact will be vulnerable to contamination and related hazards. This suggests a variety of legal issues beyond basic litigation (e.g., as related to motor vehicle accidents) including fog water collection, its safety and distribution. In order to resolve these legal and related issues there is the need for operational observations, predictions, and use of numerical models in real time and even from a hindcast perspective.

Fog Ingredients

Fog formation occurs for a wide variety of combinations of thermodynamic and radiative conditions in the atmosphere most of which are governed by synoptic scale forcing. Local variations in fog are driven primarily by local boundary layer processes and differences in microscale environments. Sufficient moisture and processes of cooling and/or lifting (inclusive of mixing) are essential for the formation of fog. These suggest three basic 'types' or categories of fog: radiational (cooling), advective (cooling and/or lifting), and combinatorial (cooling and lifting, and/or mixing).

The most critical factor for fog to exist and be sustained (as well as to be 'intense' or 'thick') is the presence of sufficient moisture, in terms of total amount and depth, while its horizontal distribution determines coverage. While sufficient moisture may also be achieved by increasing its 'effectiveness,' in other words, making use of the moisture present and realizing it through cooling and/or lifting processes to cause condensation; moisture and its realization is very much a function of meso- and microscale conditions and variations. These in turn are modulated according to microphysical behaviors that are associated with cloud droplet processes.

The presence of moisture (both condensed and uncondensed) provides the setting for the action of physical chemistries and cloud microphysics. These create subtle differences

among fogs based upon their composition and equilibrium states and can be used to distinguish fogs that, while they share synoptic and thermodynamic processes, are very different in terms of droplet size, distributions, and concentrations (e.g., continental vs marine fogs or urban continental vs forest continental fogs). The differences are most often manifest in the drop-size distributions and concentrations. In the case of fog moving from one location to another, it presents an additional complication in terms of fog maintenance and evolution. This is true from a meso- and microscale perspective as well as a physical chemistry point of view.

Fogs are also typically observed to be associated with inherently stable atmospheres. This stability may precede or occur after fog formation and often increases with the advent of fog. Even fog that is associated with strong winds, as is the case with some advective fogs, occurs in relatively stable layers of the boundary layer, which have achieved – and maintained – saturation. Other relevant factors in fog formation which may be considered as secondary in nature include vertical and horizontal distributions of temperature and moisture, orographic effects, sources and sinks of moisture and heat, land use, and surface conditions.

Fog Dynamics

There are several means of cooling an air mass, or parcel of air, that may lead to fog formation. The most obvious and most prevalent (even in the presence of cloud cover) is the diurnal loss of heat by the earth's surface and atmosphere (i.e., radiational cooling). Other means include the cooling of an air mass from below, adiabatic cooling (or mixing), the cooling of an air mass itself due to radiational release, and the evaporational cooling of air due to precipitation through a dry air layer which may induce cooling to saturation and thus result in fog. Depending on the location, time of year, and moisture availability these cooling mechanisms may lead to fog formation with varying persistence and of varying extent and intensity.

Radiational cooling is primarily diurnal in nature and is maximized during the overnight and early morning hours with minimum air and surface temperatures often occurring at or near sunrise. Although the diurnal cooling process occurs year-round, it is favored during both dry and cold seasons of the year when low level moisture may be sufficient, relatively undisturbed, and the cooling period lengthy. The dryness of the atmosphere is most typically observed above the boundary layer and allows significant radiational losses through an open atmospheric window – even in the presence of middle or high-level clouds. Radiational fogs may be brief in duration (e.g., less than 1 h) or may last several hours and are often shallow. The depth and intensity of these fog events is a function of the cooling time, and extent, and amount of moisture available. Therefore these fogs tend to be quite variable spatially across a region. It is not unusual for such fogs to also initiate dew deposition in isolated locations (or riming in the cold season or in colder climates).

The other means of cooling are of varying importance to fog formation and duration. For example, the cooling of an air mass from below is favored in locations and seasons in which the active surface layer is frozen and/or snow covered or when it

experiences a greater albedo (e.g., fallow vs the vegetative growing season). Such fogs may form and persist for hours or days at a time and cover a relatively large area with significant, albeit varying, intensities. The cooling of an air mass itself due to radiational release is typically a slow process and an important factor for persistent fogs that are maintained for extensive periods of time (e.g., sea fogs persisting from hours to days). The extent may be great but the internal variations in coverage and intensity vary largely as a function of the interactions between the air mass and the underlying surface features (i.e., the active surface of the local boundary layer). Evaporational cooling caused by precipitation falling through a layer of dry air may be sufficient to lead to saturation and fog but is typically of short duration and of limited intensity. Such cases more often result in a lowered cloud ceiling that can persist given sustaining synoptic processes (e.g., cold air damming with overrunning precipitation into an initially very dry near-surface layer of air). In the case of a synoptic scale warm front, such fog may form and persist for several days and become quite extensive and intense with minimal local variations.

The second basic means of cooling air to achieve or sustain fog formation, or for realizing the effectiveness of the moisture present in a parcel of air, is through various lifting mechanisms. These include orographic lift, frontal lift, adiabatic ascent, and mixing. In many cases, these processes involve advection and thus give rise to advective fog formation and transport. Although this implies that there are many lifting situations in which fog may form, it is clear that most of these situations involve slow vertical lifting over large horizontal distances or the relatively slow and shallow vertical mixing of two distinct air masses in the boundary layer. In the former case long lasting, extensive, and intense fogs may be expected whereas in the latter short term, shallow, and patchy fogs of varying intensity occur.

Slow vertical lift due to an upslope wind flow, parallel with the elevation gradient, will result in discrete levels of cooling and saturation with increasing distance and transport. Although this process may be slow in the initial formation of fog depending upon the amount of moisture available in the air mass (e.g., from several to nearly 24 h), it is a resilient process that can produce extended events of widespread dense fog (i.e., up to several days). Similarly, frontal lifting may produce conditions that persist for some time depending upon the rapidity of changes in synoptic features. Frontal lift is more commonly warm in nature but may involve cold frontal surfaces, which are of lesser slope than a typical cold front and/or a persistent quasi-stationary front. In both orographic and frontal cases the formation, duration, extent, and intensity of fog events is also a function of the underlying surface and its interaction with the lifted air. For example, the flow of warm and moist air across frozen or snow-covered ground – or simply upslope – increases the depth, intensity, duration, and duration of fog.

This last process is an important aspect and illustrates how two diverse air masses, initially unsaturated, may mix to form a saturated air mass. The use of saturation vapor pressure curves can be made to compare air mass properties as a function of their vapor pressures vs the absolute saturation vapor pressure for various temperatures and pressures. When a cool air mass

with relatively lower vapor pressure combines with a warm air mass of higher vapor pressure, their mixing results in saturation and thus fog. This may be seen by plotting the original vapor pressures at the individual air mass temperatures and connecting the two points with a straight line. When the line crosses the saturation vapor pressure curve, the two mixed air masses will form a saturated air mass. The manner in which these two air masses combine may be through isobaric mixing or weak adiabatic mixing. The process may also be modulated by the type and size distribution of nuclei, droplet activation, and liquid water content, in conjunction with the temperature and moisture regimes.

Lift that involves the adiabatic ascent and mixing of air is greatly dependent upon the existing boundary layer, which evolves during the mixing process to produce fog. Although of limited extent, turbulent mixing through adiabatic ascent can result in fog formation, which is typically of very short duration (i.e., less than a few hours), limited depth (e.g., ground fog), and highly variable in coverage and intensity. Such fogs may occur preceding and following the passage of weak cold fronts with limited pressure and air mass differences, and often following the passage of scattered showers or light rain, and take place in a conditionally stable boundary layer. These fogs tend to be infrequent and of short duration as the dynamics are more likely to lead to low cloud (and ceiling) formation with drizzle (although this is also determined by the nucleation process and varying drop-size distributions). In some cases these fogs may persist and thicken as the frontal boundary decays and/or becomes stationary and ingests local cloud condensation nuclei that may broaden or narrow the drop-size distribution. The processes of adiabatic ascent and mixing also play a role in the formation of Arctic sea smoke and other fogs in which the heat flux is rapid and results from temperature differentials rather than a period of radiational cooling.

Fog Evolution

Based on the preceding discussion it is clear that there are many possible synoptic, dynamic, and microphysical combinations, which may produce fog. It is therefore understandable why so many 'fog types' occur in the literature, have so much internal variability, and are studied around the world. For the same reason, it is clear that these possibilities raise the question of whether fog is readily predicted and whether one type is readily identified over another or whether one type may evolve into another. Since the orographic and frontal lifting processes are typically a gradual cooling process over long distances whereas, the radiational cooling process is gradual over time and specific to a location it is reasonable to consider various combination fogs in the same manner. It is also reasonable to incorporate the effects of cloud microphysics, the vertical and horizontal distribution of temperature and moisture, sources and sinks of moisture and heat, and land use and/or surface conditions with regard to how they modulate fog processes.

For example, given the features described above the longest lasting, most intense, deepest, and potentially most widespread fogs may occur near a coastal region with a moist onshore flow in the vicinity of a warm frontal (or topographic) or quasi-stationary boundary. This would be further enhanced or

avored if the flow of moisture was sustained, the ground frozen or snow covered (and thus the source of cooling maintained), and it was the cool season time of year. The formation and advection of sea fog – typically with a relatively larger size droplet distribution, tend to meet these criteria to varying degrees around the world and create some of the foggiest regions known. Regardless of origin, that is whether the sea fog formed first through radiational cooling or other cooling and lifting processes, it is clear that a variety of factors produces and sustains fog. This is verified by observation of the movement of fog areas and their passage from water to land.

Supporting the underlying causes of formation and growth due to cooling and lifting are the synoptic and mesoscale conditions present in the local atmosphere and their variations over time: diurnally and with dynamic evolution. These variations may occur from timescales of minutes and hours to days and thus pose both difficulties and dilemmas in all ranges of forecasting. The leading synoptic and mesoscale conditions responsible for fog formation, growth, and maintenance also interact with, respond to, and provide feedback into the local physiographic environmental features whether of natural (e.g., a region's changes in land surface cover) or of human origin (e.g., parking lots or garages). These features also complicate the physical chemistry of fog through varying radiative effects and contributions to (or deletions from) condensation nuclei (i.e., type, size distributions, and concentrations).

Synoptic and mesoscale patterns, in conjunction with the local physiographic environment, thus provide key fog mechanisms and ingredients in association with radiative, advective, and mixing processes that lead to the observed frequencies, intensities, durations, and locations of fog worldwide. These are naturally favored by select global circulation features and thus are often found as part of regional and local climate phenomena that describe the prevailing fog distribution, coverage, and occurrence. They are further enhanced – or modulated – according to a region's microphysical contributions. Thus on a global scale certain regions may be identified as prone to fog or not and with regard to fog 'severity' in terms of intensity, duration, and coverage in order to assign a risk factor or assessment. It is however important to understand that even locations that are not fog prone can be susceptible to fog impacts due to high density populations, commerce, and/or industry. Short duration, uncommon, and/or infrequent fogs may produce high impact events with significant repercussions particularly if they coincide with significant activities of a local population.

The foregoing discussion provides a 'family of fogs' in terms of formation, extent, duration, and intensity that may be expressed through conceptual models of fog dynamics. Although generous amounts of research have been accomplished and numerous modeling studies completed to reveal more explicitly the cooling and lifting processes that may produce fog, they are incomplete due to the limited integration of models that provide for improved understanding of the interaction among synoptic-dynamic, thermodynamic, physical chemistry, and microphysics. There is also the need to improve considerations of the interactions and interface between the underlying surface (and the local boundary layer's active surface) over which fog forms and the physical behaviors of fog as related to synoptic-, meso-, and microscale dynamic and thermodynamic processes in relation to local

temperature and moisture distributions. These are critical in the horizontal and vertical dimensions for better understanding and implementation of fog modification and dispersal techniques.

Fog Prediction

The advent of a more scientific and structured observational (or empirical) study of fog followed cloud classification schema and the development of more sophisticated instrumentation for study of the atmosphere, particularly on more localized scales. This phase of exploration led to improved understanding of the observed properties and behaviors of fog based on weather observation data and fog's associated characteristics as a function of dynamic processes in the atmosphere. This linkage afforded the first efforts at fog prediction in order to provide opportunity for the avoidance, mitigation, or prevention of its impacts.

Further development of these methods has included statistical and time series analyses to produce simple conditional climatologies of fog occurrence, intensity, and tendencies; as well as Markov Chain and other analytic techniques to more accurately assess fog occurrence and probability distributions for specific locations or regions (and intensity). In any of these cases, the specificity of the information is limited to the period of record and how representative each location is with regard to its surrounding area. Further specification of fog occurrence is possible when these techniques are linked to the synoptic setting or when statistical or climatic values are mapped across a region in order to infer the frequency of occurrences, intensities, and fog coverage or behavior.

However, while such findings may be applied in a predictive (or diagnostic) and deterministic manner they are limited according to an observational framework and timescale (e.g., hours or days) without full consideration of the process-oriented nature of fog formation, maintenance, evolution, and dissipation. As the observational study of fog has matured, the study of cloud physics and the microphysical processes involved in cloud growth provided distinct thermodynamic information as to the internal mechanisms and factors associated with fog formation (and dissipation) as well as its radiative impacts (as recognized many years before). This much more comprehensive insight of fog as an 'entity' phenomenon to observe and follow was also assisted by the modern development of more sophisticated instrumentation (e.g., transmissometer) to measure cloud (or fog) properties and to monitor subsequent development (or dissipation) for shorter timescales and across shorter distances.

These help to establish the sensing of fog's presence and the impact of fog intensity according to visibility criteria as linked to arbitrary interrogations vs one based on more defined impacts or meaningful thresholds. This provided more distinctive identification of fog and its variations in terms of visibility, or depth/thickness, beyond simple measurements of visual range according to predetermined target ranges. Microphysical studies have also provided sufficient evidence to explain variations in fog behavior based upon its phase composition (i.e., liquid, solid, or mixed) and its subsequent evolution. Fog drop-size distributions have been determined to

range from 1 to 10 μm according to the aerosol (or particulate) matter and the availability of moisture (e.g., mixing ratio of the atmosphere) and condensational processes. Larger sizes are preferred as fog increases during condensation processes while smaller drops dominate in dissipation.

While these also have obvious synoptic signatures as found through observational studies, they are also driven by interactions between fog and the local landscape, including local sources and sinks acting on the micro- and mesoscale. These act to contribute to locally preferred drop-size distributions with specific precipitation or deposition (or terminal velocity) tendencies. An understanding of the dependence and interaction of fog on local features has been aided by air quality and atmospheric chemistry studies (for near-surface locations) as well as the emergent air-surface and air-sea studies (over the last 20 years) that focus on boundary layer exchanges and flux behaviors. These allow a more precise explanation of fog's physical and chemical characteristics (or the statistical family of these), which modulates evolution of fog in time and space – and that create regional and local differences. Due to the physical chemistry associated with fog events, their electrical, radiative, optical, and acoustical properties also necessarily show variation.

Numerical modeling has been used more recently to demonstrate the practicality of predicting fog – and/or its impacts on visibility (or sky condition) – through surrogate parameters in a deterministic manner. For example, threshold values of mixing ratio, relative saturation levels, and cloud liquid water content have been successful in depicting fog occurrence and to a lesser extent fog coverage and intensity. Limitations to operational models have been the inability to properly portray the meso- and microscale environments as well as integrating the planetary boundary layer's characteristics and behaviors with the larger scale environment while accounting for radiative and other transfers and fluxes. Some work has been fruitful in combining these with land cover and land use information (i.e., from a Geographic Information System (GIS) perspective) to provide a more realistic portrayal of fog coverage in a region. The higher resolution examination poses additional

questions with regard to forecast validation and verification. Much work remains in order for these efforts to be reliable and timely and the use of more probabilistic approaches is needed.

In support of the avoidance, mitigation, or prevention of fog hazards, a variety of operational support and decision-making tools and information is available to forecasters as well as the affected and responding communities (e.g., aerodromes, emergency managers, or similar personnel). In some cases these are linked to, or provide data ingest for, numerical or statistical guidance packages. These are particularly effective when tied to GIS databases and decision-support software (or artificial intelligence) and are more commonly used in a military- or disaster-related type of response. The additional deployment of meso- and microscale surface-based observing networks will serve to increase the spatial and temporal acuity of data as related to fog occurrence and its evolution (and study) so that it may be more accurately detected, assessed, and compared with forecasts – particularly those based on digitized data sets (Figure 2).

Satellite and similar remote sensing platforms offer a variety of products (e.g., the 'fog product') that provide a gross estimate of fog occurrence, intensity, and coverage by channel differencing as well as through examination of sounder data to construct vertical and near-surface profiles of temperature and moisture in the atmosphere. While useful, these products only provide information after fog has formed and thus allow tracking its movements and evolution. While other parameter fields are available through satellite imagery, they provide neither adequate nor precise estimates of fog precursors for predictive purposes. Although microwave sensors and ground-based radar, lidar, and profiler platforms may offer additional information and operational support, none are presently suited or dedicated to fog detection or prediction. Additional information on atmospheric chemistry and structure is now available through several remote sensing platforms and these will provide a real-time observation profile of the physical chemistry of the atmosphere as related to fog and other phenomena or conditions in the atmosphere.

Figure 2 Satellite 'fog product' provides an observational basis for fog coverage, intensity, and duration that may aid operational prediction and nowcasting. Samples are shown from the National Environmental Satellite, Data, and Information Service – NOAA/NWS (USA); and the European Organization for the Exploitation of Meteorological Satellites (United Kingdom).

Satellite, derived remote sensing products, and aerial imagery are essential resources when analyzing fog for development, coverage, and intensity. Indeed, given the often limited spatial coverage of fog, satellite products that can analyze the temperature ranges of cloud tops can effectively accentuate an area of fog within a region of varying cloud heights and type. The higher resolution platforms continue to better specify these parameters in space and time. However, these observational resources cannot be solely relied upon for fog depiction and analysis, as fog is not accurately observed during daylight hours or when specific weather events or synoptic scale features produce upper cloud decks over areas of fog.

Fog Research and Applications

Presently, fog is known to be formed through three basic mechanisms each of which is found to a lesser or greater extent in the creation of each fog type or classification. The basic processes are radiative (cooling), advective (cooling and/or lift), and mixing (thermodynamic). Making use of the historical empirical evidence, statistical evaluations, and the principles of physical chemistry, researchers and applications specialists have used this information to enact two basic types of mitigation or prevention strategies with regard to fog hazards and a third option for use in other cases: (1) fog dispersion, (2) air quality management, and (3) special cases.

In the first case fog dispersion has focused on relatively costly mechanical means (i.e., bulk mixing) as opposed to thermodynamic and physical methods (i.e., heating and/or seeding) that have been applied predominantly at aerodrome locations. For air quality issues, emphasis has been placed on reduced exposure (e.g., avoidance by remaining indoors or masking through the use of personal filters), reduction of contributing sources, or ventilation (similar to bulk mixing) and is often a function of the population affected (i.e., receptors) and the resources required for cost-effective implementation and the likely effectiveness.

The third aspect (special cases) typically offers a mix of the foregoing methods, requires other techniques, or is not well known. These would include situations of ice or acid fog, fog water collection, smog, or fogs occurring with smoke and haze (e.g., forest fires). Related to these anthropogenic issues are the creations of artificial fogs by cooling towers and other industrial processes (through the introduction of moisture or aerosols); or those fogs made for use 'on stage' or for entertainment purposes. While most of these make use of simple ventilation techniques or equipment, these fog environments are often complicated due to the presence of other airborne aerosols which may be more readily deliquesced and thus affect the local population.

Impacts may range from ear, eye, nose, or throat ailments to chronic exposure that may need to be treated on an individual basis. Secondary impacts of fog include wet or dry deposition on plants, buildings, statues, and other surfaces causing damage due to chemical interactions (e.g., scalding). Additional fog techniques, applications, and research are those linked to fog as a water resource and the use of fog as a tactical advantage (military). Water consumption and conservation are

particularly important in less developed nations as well as in dry climates. Fog as a 'weapon' in war has been associated with creating or dispersing fog as well as artificial enhancements – including attempts at physical–chemical changes meant to attenuate radar, communication, and other signals in the battlefield – or to deliver specific aerosols, reactive agents, or gases to a target area.

Other recent scientific fog investigations have focused on the physical chemistry involved in cloud (and thus fog) processes as well as techniques for fog dissipation or dispersal based on the foregoing knowledge of fog's physical, chemical, radiative, and internal properties. Other work has been focusing on the chemical mixture of species present in fog in terms of its impacts on human (or animal/plant) respiration (e.g., acute or chronic; mortality), external contact (e.g., surface of the skin or leaf contact), and ingest (e.g., mucous membranes or eyes; fog water consumption or irrigation). In tandem with prior empirical and statistical study these are assisting in the development of a more comprehensive conceptual model of fog in terms of its characteristics, physical and chemical attributes, and behaviors.

Together these provide for integrated numerical modeling of fog with regard to its formation mechanisms, maintenance, intensity, evolution, and dissipation – particularly as related to fog's physical chemistry and its attendant optical and radiative effects. The ability to quantify these will provide an enhanced ability to model the interactions between atmospheric systems producing fog and the systems impacted by fog (i.e., human and other populations). To best represent and visualize such systems and their interactions current work has focused on artificial intelligence, impact-response models, and the use of GIS systems. It is reasonable to expect applications in catastrophe modeling in select or worst-case scenarios for real-time response and evaluation purposes.

Less obtrusive are connections that have been made with fog in the popular (and even classic) arts and literature. These include music, films, poems, paintings, and other creative works. Fog is often used to convey mystery or represent an enshrouding of truth or information that is to be concealed for often nefarious purposes. In fact, some of the arts dedicated or connected with the fog phenomenon offer clues to climate, climate variability, and climate change. These indicators can be helpful when considering climate modeling studies used to predict variations in frequencies and intensities of atmospheric phenomena such as fog to assess variations in potential or expected impacts for local communities and economies.

Fog has been observed to shape the local cultural manifestations of some societies as well as religious practices around the world. While there has been limited study of the impact of fog with regard to sociology and psychology, there is evidence that atmospheric conditions similar to fog (e.g., persistent cloudiness) do cause and/or relate to the emotional, psychological, and spiritual well-being of people. Fog may also contribute to additional health effects as related to pollen, mold and mildew, as well as disease or virus transmission. There have been suggestions that fog may pose transmission problems for high-tension power lines and interfere with reception of electronic signals.

Noctilucent Clouds

GE Thomas, University of Colorado, Boulder, CO, USA

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

Noctilucent clouds are the highest clouds on Earth, and are located in the coldest part of planet Earth, the high-latitude summertime mesopause region (80–90 km). Composed of water-ice particles, they are nucleated by meteoric smoke particles. This article discusses brief history since their discovery in 1885, occurrence patterns, the nature of the cold mesopause, methods of active and remote sounding, polar mesospheric summertime radar echoes, theory and modeling of mesospheric ice, and long-term changes of mesospheric ice clouds, possibly related to upper atmospheric climate change.

Introduction

Noctilucent clouds ('night luminous' or NLC) are the highest and coldest clouds in the atmosphere. When viewed from the ground they are referred to as NLC. Viewed from space they are called polar mesospheric clouds (PMC). Occupying a narrow (81–86 km) height zone below the high-latitude mesopause (a temperature minimum vs height, located near 88 km), NLC offer a splendid sight during summer twilights ([Figure 1](#)). They are made visible by scattered sunlight against the dark twilight sky, when the sun lies below the horizon at angles between 6 and 16°. NLC are too faint to be seen during daytime. Visible in both summertime hemispheres, they extend poleward of latitude 50°, generally increasing in their occurrence and brightness toward the pole. Ground observation becomes impossible at the higher summertime latitudes (above approximately 70–75°). Knowledge of NLC properties at the higher latitudes relies upon satellite and light detection and ranging (lidar) measurements. Information regarding these remarkable clouds, existing at the very 'edge of space' has increased enormously since their discovery in 1885, and particularly since the

space age when scientists became aware of the extremely cold conditions in the mesopause region. They are important as sensitive indicators of temperature, humidity, and dynamics, and as possible harbingers of climate change.

Brief History

Mesospheric clouds were first recognized as an upper atmospheric phenomenon in the summer of 1885, when observers throughout Britain, Europe, and Russia reported unusual cloud displays enduring through twilight, and at the higher latitudes throughout the midnight hours. F. Leslie now is given the credit for the first published report, although during that summer, many observers (Jesse, Backhouse, Tserassky, and others) witnessed nocturnal cloud displays throughout northern latitudes. Their great altitude (~83 km) gave rise to speculations that they consisted of cosmic dust or cometary debris. It was also suggested that the great Krakatoa volcanic eruption of 1883 might have injected water vapor into the mesosphere. The 2-year lag between the time of eruption and the NLC appearances of 1885 is known to be consistent with the transport time of air from the upper stratosphere near 50 km (where much of the volcanic material was deposited) to the mesosphere. The Krakatoa event was unique, in that it took place on a small island off the coast of Java, where breaching of the crater rim by seawater caused superheated steam to add to the volcanic explosivity. Its water-rich plume contrasts with all other major eruptions in the modern era whose volatile content consists primarily of sulfates and carbon dioxide. An open question is whether NLC was a pre-existing phenomenon that was only recognized in 1885, or marked the debut of a new type of cloud resulting from increasing anthropogenic activities (see Section on [Long-Term Changes of Mesospheric Clouds](#)).

In 1912, A. Wegener (famous for his advocacy of the continental drift hypothesis) proposed that NLC are composed of water-ice crystals. An obstacle to this idea was the need for either extremely cold air or very high amounts of water vapor. Later on, balloon measurements in the stratosphere showed that the upper atmosphere is very dry, and for a time the ice hypothesis was in disfavor. The water-ice theory received critical support when rocket probes in the early 1960s revealed extremely cold air at high-latitude sites during summertime,

Figure 1 Photograph of an NLC taken from Stockholm, Sweden (59.37° N, 18.06° E), on 16 July 2005. Time: 23:29 UT. Taken with a Canon PowerShot G5. Exposure time: 4 s f/3.5, focal length: 50 mm. sufficient for saturation despite the extreme aridity of the mesosphere. It was only in 2001 that satellite occultation spectroscopy confirmed the water-ice composition.

Beginning with the International Geophysical Year in 1957, networks of observers were established at locations in Europe, North America, and the Soviet Union to tabulate cloud frequency and motions and to photograph their structures. While many thousands of detailed observations became available, the interpretation of visual observations was limited until the 1960s by an ignorance of the properties of the cloud environment.

Nevertheless, these early data established the cloud seasonality, and the equatorward boundary of the 'NLC zone' in both hemispheres (which we now know is limited by warmer unsaturated air at lower latitudes). Also, their wavelike structures were among the first evidence of the presence of *gravity waves* in the upper atmosphere. Over the past four decades, ground-based data have established an apparent solar effect with approximately 10- to 11-year periodicity that has an overall inverse relationship to solar activity (conventionally described by the sunspot number). The influence of auroras, which may occur simultaneously with NLC, is of negligible importance, except during rare instances (auroral heating is confined generally to heights above 100 km). Visual and photographic observations continue today, and numerous groups monitor and archive their appearance, motions, and geographical occurrence. However, unveiling the physical nature of NLC awaited new lidar technologies and space-age observations of the properties of the previously inaccessible cloud environment.

Occurrence Patterns

Mesospheric clouds are monsoonal in character, generally existing only between mid-May and mid-August in the Northern Hemisphere, and at similar times of the year (relative to summer solstice) in the Southern Hemisphere. They are seen from all northern landmasses between 50 and 75° with a maximum occurrence rate typically ~40%. Occasionally they are witnessed at midlatitude, the 'record' being at latitude 38° in 1999, in Ignacio, Colorado, USA. In the south, there are few favorable locations, due to the scarcity of land in the NLC zone. The NLC season is about 70 days long, with peak occurrence a few weeks after summer solstice. The factors controlling their growth and decay are discussed in Section [Theory and Modeling of Mesospheric Ice Clouds](#).

The Modern Era: The Discovery of the Mesopause

Several developments led to a scientific understanding of, and renewed interest in mesospheric clouds: (1) realization that they are a possible sensitive proxy of upper atmosphere climate change; (2) discovery of intense radar echoes called polar mesosphere summertime echoes (PMSE); (3) developments in atmospheric lidar technology; and (4) the advent of rocket sounding and satellite remote sensing, revealing their global morphology and the unusual properties of the cloud environment.

A key discovery was that of the cold summertime mesopause (the temperature minimum that routinely occurs near 88 km; see [Figures 2](#) and [3](#)). This behavior is opposite to that occurring in the lower atmosphere, where summer is warmer than winter. This anomaly is a result of a general upwelling of air in the summer hemisphere (and a downwelling in the winter hemisphere) caused by the deposition of wave momentum. Atmospheric waves launched upward by disturbances in the lower atmosphere (e.g., storm fronts) influence the entire mesosphere (50–95 km), but particularly the polar environment of mesospheric clouds. Gravity waves, atmospheric *tides*, and *planetary waves* affect the thermal and dynamical states of the entire mesopause region. In their upward passage through the progressively thinner air, because wave energy tends to be conserved, the wave amplitudes grow with height. Due to the filtering action of the underlying seasonally varying winds, the waves that reach the mesopause also vary seasonally. Above about 80 km,

Figure 2 Isotherms in the 70–100-km atmospheric region, derived from a comprehensive 3D model (Thermosphere Ionosphere Mesosphere General Circulation Model) of the upper atmosphere: (a) plotted against day number and height at 67.5° N, and (b) plotted against latitude and height near northern summer solstice (day 170). Shaded areas emphasize saturation regions for water ice, i.e., regions colder than 142 K, where ice particles can exist at water vapor mixing ratios of 2 ppmv.

Figure 3 Composite of image strips of polar mesospheric clouds taken by the cloud imaging and particle size suite of UV cameras on the NASA Aeronomy of Ice in the Mesosphere satellite. Fifteen consecutive orbits of data are superimposed (separated by the 90-min orbital period), taken over 24 h on 31 December 2009. Where overlap occurs in the higher latitudes, the brightest cloud of the two strips is shown. Horizontal resolution: 5 km. Note that no data were collected in the dark region centered on the South Pole due to the satellite viewing geometry. Courtesy of the CIPS team at the University of Colorado, Boulder, CO, USA.

they often break down into turbulence, analogous to ocean breakers on a beach. The absorption of these waves causes mesospheric air to be forced equatorward in summer and poleward in winter. This seasonal forcing of the winds causes a chain of events, among them are a lifting/adiabatic cooling of the air in summer, a summer-to-winter circulation, and a sinking/adiabatic warming in winter.

The notion of seasonally and latitudinally varying *saturation* (Figure 2) is basic to the theory of ice formation (see Section [Optical Sensing of Mesospheric Clouds](#)). When air is sufficiently cold and moist, atmospheric ice is stable. When there are sufficient nucleation sites available and the air is *supersaturated*, the ice particles may grow by direct deposition of the surrounding water vapor. These ‘seed particles’ have been long believed to be meteor ‘smoke’ particles (MSPs), which result from condensation of vapors resulting from the atmospheric ablation of incoming interplanetary dust particles. Recent optical measurements from space provide strong support for this long-held hypothesis.

Rocket and Radar Sounding of the Upper Mesosphere

To gain a deeper understanding of the origin and evolution of ice particles, it is necessary to measure the thermal, chemical, electrical, and dynamical properties of their environment. This problem was first attacked through instrumented sounding rockets and continues today. Fortunately, there exist a number

of permanently staffed high-latitude launching sites that allow *in situ* measurements of the upper mesosphere. Rocket probes, radar sounding, and lidar backscattering have made it possible to measure (often with meter-scale resolution) a host of properties: wind, electron, and ion density, ionization state, particle size and density of both ice and mesospheric aerosols, charge state, etc.

It is important to mention the closely related phenomenon of PMSE. The discovery in the early 1980s of very high frequency radar echoes from the high-latitude summertime mesopause region added an extra dimension to NLC studies. Radar does not interact directly with ice particles, but with highly structured variations in the refractive index of the free electron density. The prevailing theory combines neutral air turbulence with reduced electron diffusivity owing to ice particles, which become charged by electron attachment. Subsequently these charged ‘heavy’ particles influence the remaining free electrons by Coulomb interaction. The morphology of PMSE is similar to that of NLC, but the structures are thicker, extending from the lower border of saturation to above the mesopause (Figures 2 and 4). Because of their greater sensitivity to the more numerous small particles, PMSE are often seen when NLC are not detected. Also when they are present, the thin NLC layers (a few kilometers thick) are often detected near the lower PMSE boundary. Only the largest particles in the particle size distribution (equivalent radii, $r > 25\text{--}30\text{ nm}$) appear as NLC layers to lidar backscattering, owing to the strong dependence of light scattering on particle size (as described in Section [Optical Sensing of Mesospheric Clouds](#), highly sensitive near-IR measurements of PMC from space detect ice throughout the saturated region). It should be mentioned that both PMSE and NLC are quite sporadic in occurrence. The morphology of PMSE and ice particles are intimately related but their detailed relationship is not fully understood, and is a subject of continuing research.

Optical Sensing of Mesospheric Clouds

Five basic types of optical measurements are used in the study of mesospheric ice clouds. All but one type relies upon the scattering of solar light: (1) Ground-based NLC sightings are usually visible only near the horizon where the line-of-sight optical paths are longest. Such data are most useful for seasonal, morphological, and long-term trends. Time lapse movies are becoming scientifically valuable in revealing complex dynamical changes not obvious in still pictures; (2) Rocket-borne photometers flown through the region; (3) Active methods which also rely upon the same basic scattering process, but utilizing a series of powerful *laser* pulses (light amplification by stimulated emission of radiation); (4) Measurements from orbit in the visible and ultraviolet (UV) spectral ranges; (5) Methods relying upon precision measurements from space of the attenuation (extinction) of sunlight passing tangentially through the cloud layers.

Lidar Observations

Lidar is an active technique for observing NLC from fixed ground-based sites. Three permanent Northern Hemisphere

Figure 4 Left: Schematic diagram of the microphysics of mesospheric ice particles. Temperature is shown by the black curve. Meteor smoke particles (MSPs) are shown as purple dots, and ice is shown in blue. Where supersaturation occurs (to the left of the dashed green line showing the frost point temperature where the air is barely saturated), ice forms on the largest MSP. Eddy diffusion carries the small particles downward into a less saturated, but moister environment, where the ice particles may grow to sizes that are optically visible, and constitute a narrow noctilucent cloud (or polar mesospheric cloud) layer near 83 km. Ice particles exit the region within hours by sedimentation and evaporate where the temperature exceeds the frost point. This diagram ignores many other processes such as horizontal transport of ice by winds and strong gravity wave effects (see text). Figure adapted from M. Rapp of the Leibniz Institute of Atmospheric Physics at the Rostock University, Kühlungsborn, Germany, with permission. Right: SOFIE data (see Section [Optical Sensing of Mesospheric Clouds](#)) from 26 July 2007 (orbit 782) for ice particle radius (nm) and concentration (cm^{-3}). For SI units (m^{-3} , multiply blue curve values by 10^6).

lidars, at Sondrestrom and Andoya (Norway), at Fairbanks, Alaska, USA, and in the south, at Davis Station, Antarctica, routinely measure NLC. Of course, lidars can only measure NLC when they are not obscured by tropospheric clouds. The Institute of Atmospheric Physics (IAP) in Germany operates the Rayleigh/Mie/Raman (RMR) lidar at the Arctic Lidar Observatory for Middle Atmosphere Research (ALOMAR) at Andoya (69.3° N). Analysis of three-color ALOMAR lidar backscattered light from the brighter clouds determines NLC mean particle size (30–65 nm range), size dispersion, and ice water content. The long-term data sets have defined the local time dependence of cloud occurrence frequency, which follows a diurnal (24-h) period, at least at this location ([Figure 5](#)). Predictions of the Leibniz-Institute Middle Atmosphere (LIMA) model (see Section [Theory and Modeling of Mesospheric Ice Clouds](#)) suggest that the changes are driven by the atmospheric thermal tide.

Satellite Observations

In 1969, satellite-borne instruments intended to measure airglow revealed solar scattered light from a daytime mesospheric cloud layer extending to near the geographic pole. This discovery, and subsequent satellite experiments, showed that mesospheric ice clouds (now referred to as PMC) increase in brightness and occurrence rate with latitude toward a maximum at the pole. The clouds were found to exist over similar latitude ranges in both northern and southern summers. US Astronauts and Soviet/Russian Cosmonauts are quite familiar with the phenomenon, reporting (and later photographing) PMC from space. Following these early measurements, data have been collected from increasingly

sophisticated satellite instrumentation. A few highlights follow.

A goal of the Odin satellite mission (2001) was to study the cold mesopause region. Recently, analysis of the data from the Odin Optical, Spectroscopic, and Infrared Remote Imaging System (OSIRIS) spectrometer experiment has revealed a remarkable ‘teleconnection’ control of PMC from the *opposite* (winter) stratosphere (15–50 km). This connection occurring over tens of thousands of kilometers is particularly striking in affecting the southern PMC, since the northern stratosphere is more dynamically disturbed in winter than the southern winter. In addition, a second dynamical forcing agent has been found using data from Aeronomy of Ice in the Mesosphere (AIM) Cloud Imaging and Particle Size (CIPS) (see below) and OSIRIS. The seasonal start date of southern PMC appears to be tightly controlled by the timing of the winter–summer stratospheric wind transition (the ‘breakdown of the polar vortex’).

The NASA Aeronomy of Ice In the Mesosphere (AIM, 2007) is the first satellite mission dedicated to the study of PMC. The AIM CIPS experiment measures PMC scattered brightness in the UV, with a 5-km resolution ([Figure 3](#)), PMC spatial distribution over most of the polar region, and the spectrum of gravity waves as they interact with cloud brightness. A surprising result is that cloud structures change nearly completely over consecutive 90-min orbital periods, indicating shorter cloud lifetimes than anticipated from theory. CIPS revealed that large-scale nearly circular ‘voids’ occur in PMC images, whose origin is yet to be determined. Analysis has shown that PMC have similar fractal dimensions as tropospheric clouds, an important clue suggesting that there are common meteorological processes in both types of clouds. Analysis of wave structures in the CIPS large-field images has resolved a wealth and diversity

Figure 5 Diurnal variation of noctilucent clouds occurrence determined from Arctic Lidar Observatory for Middle Atmosphere Research Rayleigh/Mie/Raman (RMR)-lidar (using the brighter cloud data) and atmospheric parameters at 83-km altitude during times of lidar measurements: temperature (red squares) and zonal wind (green filled triangles) as calculated by the Leibniz-Institute Middle Atmosphere (LIMA) model, and zonal wind as measured by the medium frequency (MF) radar (green open triangles, dashed line). RMR and LIMA data are integrated from 1997 to 2010, MF data from 1999 to 2010. Vertical bars indicate confidence limits for the occurrence at 95% level and errors of the mean for temperature and wind. Figure by J. Fiedler of the Leibniz Institute of Atmospheric Physics at the Rostock University, Kühlungsborn, Germany, with permission.

of coherent gravity wave activity extending over both the northern and southern polar summer regions with horizontal scales ranging from tens to several thousand kilometers. The AIM Solar Occultation For Ice Experiment (SOFIE) conducts high-precision solar occultation measurements in 16 spectral bands to retrieve vertical profiles of temperature, O_3 , H_2O , CO_2 , CH_4 , NO , and PMC extinction. Due to its unprecedented sensitivity, SOFIE data confirmed the expectation from PMSE (see Section [The Modern Era: The Discovery of the Mesopause](#)) that ice is distributed throughout the saturated region. SOFIE observations have revealed the size, shape, concentration, phase, and temperature of mesospheric ice (see [Figure 4](#)). Ice and water vapor are measured simultaneously in a common volume, revealing in detail the ‘freeze-drying’ process, and rehydration below the cloud region. SOFIE made the first satellite observations of MSP throughout the upper stratosphere to 85 km. Observations in the 330–1037 nm wavelength range have significantly narrowed down the candidates for the MSP composition (carbon, wüstite, magnesiowüstite, olivine, or magnetite). SOFIE measurements also reveal that the ice particles comprising PMCs contain small amounts of smoke (0.02–2% by volume), and that the smoke composition contained in ice is consistent with carbon, wüstite, or magnesiowüstite.

Large rockets affect PMC directly through their exhaust products. The NASA Space Shuttle injects large amounts of water into the lower thermosphere. The water-rich plume is sometimes transported many thousands of kilometers toward the poles, and when the midlatitude launches occur in summer, impulsive increases in PMC brightness are observed several days afterward in satellite PMC data. The mechanism of the fast transport is still not understood, and it remains an open question whether growing amounts of space ‘traffic’ has contributed to the apparent long-term trends of PMC brightness and occurrence (Section [Long-Term Changes of Mesospheric Clouds](#)).

Theory and Modeling of Mesospheric Ice Clouds

The ‘microphysics’ of ice formation and evolution involves the nucleation, growth, transport, and decay of ice particles. The details of the prevailing theory of the nucleation process are sketchy, beginning with the values and seasonal dependence of the incoming meteoroid flux and composition, and continuing with their ablation and subsequent coagulation. The classical ‘liquid droplet’ theory predicts that only the largest MSP sizes (>1.3 nm) have a low enough ‘energy barrier’ that water vapor will deposit on their surfaces more rapidly than they will sublimate. Fortunately, modeling cloud ice mass is quite insensitive to the number of seed nuclei assumed (which is poorly defined in the cloud region). This somewhat magical, but convenient fact is explained as follows. Because nucleation rates are rapid in the upper cold region ($T < 130$ K), the number of particles is very large ($\sim 10^9$ m^{-3}), but their size is limited to tens of nanometers due to the limited water supply. The creation of ice ‘freeze dries’ the mesopause region. Particle sedimentation is too slow to transport the particles downward where clouds form. The cold nucleation region near the mesopause is thus weakly coupled to the cloud region below. These small particles are transported downward mainly through *turbulent eddy diffusion* ([Figure 4](#)), and not because of sedimentation, as previously thought. (The turbulence is thought to be a result of the gravity wave ‘breaking’ process, mentioned in Section [The Modern Era: The Discovery of the Mesopause](#).) A small fraction is transported into the warmer (temperature approximately 140–145 K) and slightly saturated region. The smallest particles reaching this lower region sublimate and contribute to the hydration of the region. The larger particles ($r > 10$ nm) grow rapidly due to the exponential increase of water vapor, and because there are so few of them ($\sim 10^8$ m^{-3}), they grow into optically visible clouds ($r > 25$ –30 nm) without seriously depleting the available water. The total ice mass and also the cloud brightness are limited by the number of ice particles delivered to the cloud region, rather than the amount of available water. The lifetime (a few hours) of the visible cloud is limited either by sedimentation into the warmer air, or by the duration of saturation. The passage of large-amplitude gravity waves through the region somewhat alters this simple picture of an upper region filled with cloud ‘embryos,’ and a lower region occupied by larger visible ice particles. The entry of the cold phase of the wave into the cloud region will lower, and blur, the ‘boundary’ of the two regions, so that nucleation of new particles can occur lower down. The entry of the warm phase will raise the boundary. Modeling of effects of these strong waves produce an overall increase of ice particle number.

Thus the key to understanding many of the observed properties of clouds is the dynamical variability of the medium, on many scales. Gravity waves cause horizontal variability on scales from tens to hundreds of kilometers. These waves ‘stir up’ the medium, modifying the temperature and wind speeds on timescales of tens of minutes to hours. In addition, where they become unstable, the waves dissipate their energy and cause further stirring due to the creation of turbulence, which occurs on scales of tens of meters. Even a few Kelvin of temperature variance can lead to large differences in cloud properties. [Figure 3](#) illustrates that PMC structure occurs on scales down to

at least 5 km, and are quite likely sensitive tracers of temperature variability on similar spatial scales.

Long-Term Changes of Mesospheric Clouds

Long-term trends are of two types: (1) cyclical, with 10- to 11-year periodicity, and (2) secular trends, which are only noticeable after several decades of observation. Identifying secular trends are of great interest, in that they could be caused by anthropogenic or naturally occurring climate change. Two types of data are relevant. The first involves longer duration ground-based results. The second type is from satellites, for which one suite of measurements in particular has the record length necessary to address both cyclical and secular tendencies.

Two sets of NLC observations from the UK and Denmark (latitudes from 51° to 61° N) since 1964, and from near Moscow, Russia (56° N), since 1962 constitute the longest continuous records. The conventional NLC 'climate index,' N , is the total number of nights NLC are spotted within a season, and ranges from as few as four nights per season to as many as 40 or more. The observed cyclic behavior is dubbed the 'quasi-10-year oscillation,' since the derived period (10.4 years) is less than that of the 11-year solar cycle. Within a few percent neither the mean brightness nor N shows significant increases over the last 45 years.

Satellite observations have several important advantages over ground-based data in identifying long-term changes in PMC, covering both hemispheres, all longitudes and most polar latitudes. They are immune to tropospheric cloud cover and provide quantitative photometry. Disadvantages are that their high-inclination orbits are tied to a fixed, or slowly varying solar local time, and analysis of time series are subject to mixing up possible long-term variations in the tidal signature (see Figure 5). Also, most satellite instruments generally have short lifetimes, usually less than 10 years, precluding separation of cyclical and secular trends.

Of greatest value for long-term trends are data from the Solar Backscatter Ultraviolet (SBUV) Spectrometer. Seven nearly identical SBUV instruments have been flown since 1979 in Sun-synchronous orbits, with the objective of monitoring long-term changes in stratospheric ozone. Fortunately, shorter wavelength data also contain signatures of bright PMC. A time series of average PMC average brightness for 1979–2010 is shown in Figure 6. PMC data show both cyclical and secular trends. Similar but smaller trends apply to the southern PMC. Frequency of bright cloud occurrence also shows significant secular trends (with 95% confidence) in both hemispheres. The apparent contradiction between the ground-based and low-latitude SBUV trends is not understood.

Attributing the trends to causal forcings is the task of models. Two different general circulation models including ice formation now reproduce the SBUV trends. The LIMA model

Figure 6 Annually averaged Northern Hemisphere polar mesospheric clouds brightness (squares) Solar Backscatter Ultraviolet data vs year through 2010. Dashed curve: a multiple regression fit of the data, including a constant, a term proportional to solar Lyman alpha irradiance, and a linear secular increase. The latter value is $+3.5 \pm 1.7\%$ per decade (exceeding 95% confidence). The Southern Hemisphere trends are smaller ($+2.3 \pm 1.2\%$ per decade), but still significant. Provided by M. DeLand of Science Systems and Applications, Inc., Lanham, MD, USA, with permission.

was developed by the IAP, and the Whole Atmospheric Community Climate Model (WACCM) by the National Center for Atmospheric Research (NCAR) in Boulder, CO, USA. The versions that include mesospheric ice formation, the IAP LIMA/ICE model and (the latter developed jointly by NCAR and the University of Colorado at Boulder) take different approaches for simulating long-term changes, yet arrive at similar results. Both cyclical and secular trends of modeled PMC match remarkably well the SBUV data set (Figure 6). In both models, the cyclical effect is caused by solar cycle changes in the UV photodissociation rate, reducing water vapor and thus cloud brightness during solar maximum. The IAP group attributes most of the secular trend to stratospheric ‘contraction,’ since their lower boundary is driven by meteorological data, and not by greenhouse gas (GHG) forcing. However, GHG forcing effects are implicitly included in their lower boundary conditions, since the known cooling trends are contained in the stratospheric forcing. In contrast, WACCM-PMC models the entire atmosphere, and so the changes are a result of GHG increases throughout the atmosphere. WACCM-PMC also includes increases in chlorofluorocarbons (CFCs), which destroy ozone and create the ozone hole. The long-term decline in ozone heating results in a cooler PMC region. However, the separate roles of CO₂, CH₄, and CFCs are yet to be sorted out. The attribution issue is yet to be resolved, but the analysis tools are now available to determine the origin of changes revealed in long-term data sets of PMC. As mentioned in Section [Optical Sensing of Mesospheric Clouds](#), the question of whether increased space traffic has contributed to the observed SBUV trend is still open. Much remains to be learned.

Stratus and Stratocumulus

Synopsis

Stratus and stratocumulus clouds are two dominant types of low stratiform cloud that together cover 30% of the Earth's surface. Both are thin boundary layer clouds that frequently occur as the sole cloud type under conditions of large-scale subsidence and strong lower-tropospheric static stability, but they can also exist mixed with higher clouds during disturbed periods. Stratocumulus are convective clouds driven largely by the emission of infrared radiation from cloud top and from latent heat release. Stratus, on the other hand, are largely free of convective overturning. Both are typically very thin clouds that can extend horizontally for large distances. Stratocumulus frequently produce light precipitation often in the form of drizzle. Because they strongly reflect solar radiation, stratus and stratocumulus exert an important impact on climate.

Stratus and stratocumulus clouds are the two most common genera of low stratiform cloud by area covered. They often occur under fair weather conditions, and in this way they are distinct from a third low stratiform low cloud type called nimbostratus. However, stratus and stratocumulus also commonly occur during periods of large-scale ascent, under which conditions they coexist with clouds at other levels. In stratocumulus, the cloud layer is comprised of a multitude of individual convective elements giving the layer a lumpy morphology. Stratus, in contrast, is typically more featureless than stratocumulus because of a lack of active convective elements. The layering in both stratus and stratocumulus is commonly maintained by a capping inversion immediately above the cloud top. The temperature inversion can sometimes be strong and is often only a few meters to tens of meters thick. Both stratus and stratocumulus clouds are usually contained in the atmospheric boundary layer.

Stratocumulus is the most common cloud type globally (Warren et al., 1986, 1988), covering approximately one-fifth of Earth's surface in the annual mean (23% of the ocean surface and 12% of the land surface). Stratus clouds cover roughly 10% of the Earth's surface (12% of the ocean surface and 5% of the land). Because stratus and stratocumulus clouds are so common and because they strongly reflect incoming solar radiation, these clouds are important for Earth's radiative balance and therefore climate. In addition, accurate prediction of daytime temperature over many land areas relies on models being able to accurately represent stratus and stratocumulus and their diurnal variability.

Stratocumulus commonly occurs under conditions of large-scale subsidence and strong lower-tropospheric static stability. In the subtropics and tropics, they tend to occur in semi-permanent sheets over the cold eastern ocean basins under the downward branches of the Hadley and Walker circulations (Figure 1(b)). In midlatitudes, stratocumulus sheets tend to be more transient and are typically associated with transient ridges in passing planetary waves, and in winter they commonly form in offshore or polar cold-air outbreaks.

Like stratocumulus, stratus clouds also tend to form under conditions of large-scale subsidence and strong static stability. Whereas stratocumulus dynamics are primarily driven by convective instability caused by cloud top thermal infrared

radiative cooling, stratus tends to be free of convective overturning and so is typically associated with a stable temperature profile in the boundary layer. Stratus may be formed from warm air passing over a cold ocean (warm advection), which can lead to condensation without the need for convective

overturning. This can lead to the formation of fog, a cloud genera distinct from stratus and stratocumulus, but wind-driven mixing can elevate the base of the fog layer, leading to stratus. Stratus associated with warm advection is most common over the storm track regions of the Atlantic, Pacific and Southern Oceans, where it can exist 20–30% of the time in both summer and winter months (Figure 1(a)). Over land, stratus is fairly uncommon and is concentrated in regions influenced by extratropical storm tracks. Stratus is also uncommon over the warm tropical and subtropical ocean, but is more common over the cold subtropical oceans (Figure 1(a)). However, in these regions cold advection and strong thermal infrared cloud top cooling under a dry free-troposphere often transforms stratus clouds into stratocumulus by encouraging convective instability.

Structure

Stratocumulus clouds are typically 200–400 m thick and usually occur at the top of the boundary layer below a thermal inversion. It is remarkable that such a thin cloud can extend practically unbroken for a thousand kilometers, but strong negative feedbacks exist to constrain cloud thickness. First, thicker clouds produce drizzle, which can act to reduce condensate and serve as a negative feedback on thickness. Second, and likely the most important in cloud layers without drizzle, the cloud thickness is limited by the entrainment of dry, warm air from the free troposphere, which acts to dry out and thin the cloud. Cloud top entrainment in stratocumulus is driven by the turbulence created by the clouds themselves. Thicker stratocumuli generate more turbulent kinetic energy than thinner ones, so that the strength of cloud top entrainment increases with stratocumulus cloud thickness. The cloud thickness-turbulence-entrainment loop also serves as a strong negative feedback on stratocumulus cloud thickness.

Stratus is often confined to within a few hundred meters of the surface, but can exist at many levels often in conjunction with more vertically extensive cloud systems such as warm fronts and mesoscale convective systems (often as stratus fractus). Stratocumulus top heights are typically 500–2000 m over the Earth, confined mostly by the inversion height of atmospheric boundary layers. Stratocumulus clouds can exist within both well-mixed and intermittently coupled boundary layers. Stratocumulus clouds help to keep the cloud layer relatively well-mixed, but as the boundary layer becomes deeper, the cloud layer frequently becomes disconnected from the surface mixed layer. Coupling of the stratocumulus and surface layers in this case is intermittent and is provided by patches of cumulus clouds that originate at the top of the surface mixed layer and in many cases reach up into the stratocumulus deck. Stratocumulus in coupled, well-mixed boundary layers tends to be more horizontally homogeneous than that in intermittently coupled boundary layers, where stratocumulus tends to exist in patchy regions surrounding the regions of cumulus coupling. Stratus clouds tend to only exist within thermally stratified layers, sometimes as the result of large-scale ascent associated with midlatitude cyclones or orography.

Because stratocumulus are low clouds, most stratocumulus contain liquid condensate, but ice can also be present when the

cloud top temperature is sufficiently supercooled. It is unlikely that completely glaciated stratocumulus clouds can produce sufficient turbulence to maintain the cloud against precipitation losses. Observations of low, stratiform clouds in the Arctic suggest that most contain liquid water even at temperatures well below freezing. In general, liquid water increases upward from cloud base and usually maximizes near cloud top, consistent with what one would expect to occur in a well-mixed layer where water mixing ratio is constant and temperature decreases with height. The turbulent eddies in stratocumulus layers are initiated by cloud top longwave cooling but are strengthened by latent heat release in updrafts and evaporative cooling in downdrafts. The distribution of vertical wind speed is negatively skewed near cloud top, with strong downdrafts and relatively weak updrafts, but the eddies become more symmetric further down in the cloud layer. The strongest vertical winds are usually found near the top of the cloud layer. Typically, updraft speeds in stratocumulus are $0.1\text{--}1\text{ m s}^{-1}$, but are weaker in stratus clouds, where shear-generated turbulence may produce small-scale, weak eddies that can drive a degree of overturning.

The tops of stratocumulus clouds are typically flatter than the bases. This is particularly true over oceans under conditions of large-scale subsidence where time has been allowed to develop a strong thermal inversion atop the clouds that acts to suppress the vertical extent of the cloud tops. Over land, both cloud bases and tops can exhibit comparable variability. Stratus clouds also often have flat tops, and are usually distinguished from stratocumulus by their relatively flat bases.

Stratocumulus clouds exhibit horizontal structure on the scale of the largest turbulent eddies. This is most strikingly seen with the naked eye or in photography of cloud tops and bases, which show clear hummock structures on scales of a few hundred meters. Visible satellite imagery (e.g., Figure 2)

Figure 2 Visible satellite image from the NASA Moderate Resolution Imaging Spectroradiometer to the west of South America showing closed and open cell stratocumulus clouds. A band of stratus clouds is present along the Peruvian coastline. The image scale is approximately 2000 km across. Image from the NASA MODIS Rapidfire archive.

indicates, however, that stratocumulus cloud fields also exhibit a significant degree of structure and organization on scales of tens of kilometers, i.e., on mesoscale-beta and mesoscale-gamma scales. Stratocumulus clouds over oceans tend to organize into one of two common forms: closed and open mesoscale cellular convection (Atkinson and Zhang, 1996). The cells vary in horizontal scale but tend to be 5–50 km in size, with the depth of the stratocumulus-topped boundary layer in which they exist being the primary determinant of cell size (Wood and Hartmann, 2006). Although the theory for such mesoscale organization is not complete, it is clear that diabatic effects and their effects on boundary layer turbulence are the primary drivers leading to an upscaling of turbulent kinetic energy from the large eddy scale to the mesoscale. One example of this is that the evaporation of precipitation below cloud can drive cold pool formation that suppresses small-scale eddy overturning but encourages the formation of mesoscale circulations. Stratus clouds do not generate their own mesoscale variability, but may exhibit such variability if it is imposed by the large-scale flow.

Formation, Maintenance, and Transformation

Stratus and stratocumulus can form from the cooling or moistening of a clear boundary layer. Clear sky longwave cooling drives the clear boundary layer toward condensation by lowering its temperature toward the dew point temperature. Condensation will typically first occur in a thin layer near the top of the boundary layer. This cloud is initially stratus because it likely contains little convective instability. But quickly the cloud layer typically grows sufficiently thick to become strongly emissive in the thermal infrared, so that radiative cooling becomes increasingly concentrated in a thin layer near cloud top. This cooling drives the typical form of ‘top down’ convection commonly found in marine stratocumulus. Over land, surface fluxes are often strong enough to compete with cloud top cooling, and so turbulence in continental stratocumulus tends to be more strongly surface-driven than is the case over oceans. Stratocumulus can also emerge from the transition of another cloud type, most commonly cumulus and stratus.

Stratus clouds, in addition to being formed by radiative cooling of a moist clear layer, can be formed by lifting of moist air masses in regions adjacent to fronts or over orography, and by warm advection of a moist layer over a cold surface. Because thermal infrared absorption from liquid water is so efficient, many stratus clouds are unstable, because, as the cooling strengthens, condensate builds up, longwave cooling further strengthens, and the layer becomes increasingly susceptible to convective overturning (hence stratocumulus formation). In this way, stratus clouds can be seen as transient in nature, the thermodynamics favorable for their existence only existing in fleeting pulses. The resulting stratocumulus sheet tends to be a more robust cloud system. On the other hand, stratocumulus can form as the result of the spreading of shallow cumulus clouds. Although unusual over the ocean, this occurs quite frequently over extratropical land areas. For this to occur, the cumuli need to be strongly capped by a thermal inversion, and surface driving needs to be sufficiently strong.

Stratocumulus cloud layers are maintained by an energetic balance between radiative cooling and surface and cloud top entrainment warming, and by a moisture balance between surface moisture fluxes and drying from cloud top entrainment. Precipitation, when present, can affect both energy and moisture budgets in sometimes complex ways.

Stratocumulus and stratus clouds frequently exhibit strong diurnal variability, primarily as a result of the daytime absorption of solar radiation near cloud top. This serves to weaken the overturning from cloud top longwave cooling during daytime, which weakens the ability of the stratocumulus to maintain a well-mixed boundary layer. The suppression of mixing during daytime can help to decouple the cloud from its surface moisture source, which can result in cloud thinning and also breakup. Observations show that, as a result, stratocumulus clouds are more turbulent, thicker, and contain most condensate at night. Studies show that nighttime stratocumulus can contain 50% more condensate than during the day. The higher nighttime condensate amounts help drive nighttime precipitation maxima. Typically, as stratocumulus breaks up during the day, it tends to be replaced by either fair weather cumulus clouds or by a broken stratocumulus deck with cumulus clouds rising into it. Stratus clouds often dissipate during daytime by direct heating of the cloud layer by solar absorption and subsequent reduction in the relative humidity.

Just as the diurnal breakup of stratocumulus clouds during the day is caused in large part by the transition from a well-mixed to an intermittently coupled boundary layer, so too is the climatological transition from subtropical stratocumulus to tropical trade cumulus over the eastern ocean basins. In the latter case, the transition is driven by increasing surface latent heat flux as the ocean warms below. This drives stronger entrainment of warm, positively buoyant free-tropospheric air, which becomes increasingly difficult to mix down through the entire boundary layer. As a result, the boundary layer transitions from a shallow, well-mixed layer dominated by relatively homogeneous stratocumulus clouds, to a deeper, intermittently coupled boundary layer containing cumulus clouds rising into a layer of stratocumulus. As the transition progresses, the cumulus clouds become increasingly unable to supply sufficient moisture to the stratocumulus layer to offset drying from cloud top entrainment. As a result, the stratocumulus layer thins (Figure 3) and eventually dissipates completely leaving trade cumulus clouds as the sole clouds in the boundary layer.

An alternative fate for well-mixed stratocumulus can occur if sufficient precipitation is produced to generate evaporatively driven cold pools. The subcloud cooling of evaporating drizzle drops, coupled with the dynamic forcing from cold pools undercutting and lifting near-surface air, helps drive locally strengthened regions of ascent that can spawn cumulus clouds that further enhance precipitation formation. The efficient removal of precipitation from the stratocumulus layer can result in thinning and dissipation, with the result being mesoscale cell walls containing thick clouds and cell centers with very thin and broken clouds. This precipitation-driven transition from closed to open cells can be very sharp in space (Figure 2) and time.

Figure 3 Photograph showing thinning sheet of stratocumulus clouds over the southeastern Pacific Ocean with penetrating solar rays. Image taken as part of the NOAA stratus research cruises to the southeastern Pacific.

Microphysical Processes

Warm rain formation in stratocumulus first requires the formation of precipitation drop embryos. These are formed from a small subset of cloud droplets lucky enough to undergo a few coalescence events. Because the probability of coalescence and the speed at which a droplet falls both increase strongly with droplet size, the lucky drops can grow rapidly given a sufficient quantity of cloud droplets to collide with. As they grow, these embryonic drizzle drops begin to fall faster than cloud droplets because a drop's terminal speed increases rapidly with its size. The embryos begin to collect cloud droplets as they fall through the cloud layer (a process termed accretion) and can grow rapidly to sizes of several hundred micrometers. Precipitation formation in stratocumulus is strongly dependent upon the availability of condensate in the column (i.e., cloud thickness) and also upon the ability of the cloud to produce large cloud droplets capable of producing precipitation embryos.

The concentration of cloud droplets in stratocumulus clouds is determined by the availability of soluble aerosol particles (most commonly natural and anthropogenic sulfate aerosols and sea-salt) and by the strength of the updrafts. In stratus, updrafts are particularly weak, whereas convective elements in stratocumulus tend to produce stronger updrafts that results in a higher concentration of cloud droplets being formed for a given aerosol population. The concentration of cloud droplets is particularly important because it strongly impacts the resulting size of droplets for a given amount of condensate. The impacts of cloud droplet size are twofold: first, for a given condensate amount, smaller droplets lead to a greater overall surface area and a higher cloud albedo. Second, because the precipitation process in stratocumulus is caused by the collision and coalescence of cloud

droplets, and because smaller droplets collide less efficiently than larger drops, the production rate of precipitation embryos is faster in a cloud with a low cloud droplet concentration and larger droplets. Thus, observations indicate that the rate at which precipitation falls from stratocumulus is quite strongly dependent upon the cloud droplet concentration. As discussed above, precipitation can exert a significant impact on the dynamics of stratocumulus clouds, and so it is necessary to consider the impact of aerosol particles to understand the degree to which stratocumulus clouds precipitate. Satellite radar data indicate that stratocumulus over remote ocean regions, where the aerosol concentration is particularly low, precipitate more efficiently than those near the coast. Indeed, over land many stratocumulus clouds do not precipitate at all. Regardless of the cloud droplet concentration, stratocumulus clouds thinner than ~ 200 m do not generate much precipitation.

Mixed-phase stratocumulus and stratus, however, can precipitate via the ice phase. Because the growth of ice under water-saturated conditions is quite rapid, collision-coalescence is not necessary for precipitation formation in this case because ice crystals can grow to precipitation size (~ 1 mm) by vapor deposition. However, the availability of liquid water can still influence the precipitation in this case through the riming process: ice crystals collecting cloud droplets as they fall through the liquid cloud. Precipitation formation in mixed-phase stratocumulus and stratus remains poorly understood primarily because the production rate of ice crystals and the heterogeneous nuclei on which they form are not well known.

Precipitation in stratocumulus is horizontally heterogeneous, with a strong tendency for precipitation to be sharply concentrated in regions where the clouds are thickest. Precipitation drops in stratocumulus clouds grow to maximum sizes

of ~ 1 mm, but most are in the range 50–500 μm . As such, stratocumulus produce both drizzle (drops smaller than 500 μm) and, in some circumstances, light rain. Drops smaller than ~ 300 μm usually evaporate below cloud base; larger ones often survive the fall to the surface. The extent to which precipitation evaporates or reaches the surface has an important impact on the moisture and energy budgets of the boundary layer and upon cloud dynamics.

Stratus and Stratocumulus Clouds and Climate Change

Because stratus and stratocumulus together are so plentiful, they exert a strong cooling impact on the climate system by reflecting a large amount of sunlight back to space. It is well understood that relatively small changes in the coverage of these clouds or the brightness of the existing clouds can help to enhance or offset the warming caused by increasing greenhouse gases. Although consensus across models is still relatively poor, current climate modeling suggests that stratus and stratocumulus cloud cover will likely decrease slightly in future, thus enhancing greenhouse warming. However, the fact that stratus and stratocumulus clouds are so thin makes it particularly challenging to represent these clouds in low-resolution climate models.

In addition, the anthropogenic impacts of increasing aerosol concentrations may enhance the albedo of these clouds. These ‘aerosol indirect effects’ are thought to offset

anthropogenic greenhouse warming by as much as 25–50%, but these estimates are highly uncertain due in major part to a poor fundamental understanding of how to represent the myriad processes through which stratus and stratocumulus clouds interact with atmospheric aerosol particles.

Synopsis

Glaciers are distinct features of Earth's climate system and, combined with sea ice, form the cryosphere. Glaciers currently exist around the globe from the polar regions to tropical high altitudes. Although composed of ice, they are very dynamic and play an extremely important role in shaping the land surface in alpine regions as well as regulating regional climate. Glaciers also play a fundamental role in providing freshwater resources to a significant fraction of the world's population. Monitoring of glaciers is an important component in the effort to determine the effects and ramifications of climate change.

Introduction

Water is arguably the most important component of our climate system. It is responsible for all of our freshwater and agriculture, our oceans and marine ecosystems, and it contributes to our daily weather. Water plays such a primary role on our planet because it can exist in all three phases given our Earth's temperatures and pressures. All substances have a vapor, liquid, and solid phase with transitions between these phases regulated by the thermodynamics of temperature and pressure. Within our climate system, water can naturally cross these thermodynamic thresholds using energy to evaporate water from the oceans or to melt ice, or releasing energy to form precipitation or ice. The energy required to evaporate water or to melt ice comes primarily from solar energy, and the energy released during condensation or ice formation heats the atmosphere, ocean, or a glacier itself depending on where these processes occur.

A glacier is an ice mass that has formed over a long period of time through snow accumulation. Repeated snowfalls compress the snow underneath, increasing its density by squeezing out air pockets. This compaction of snow into firn (a granular state between snow and ice) takes years and, usually over decades, the firn compacts into ice. The geographic

location of a glacier is therefore dependent on both temperature and net snowfall amounts. If it is too warm, the snowfall melts before it can be compacted to ice. In tropical and subtropical regions, these conditions are only satisfied at high elevations and hence glaciers exist at low latitudes only in the high mountains of the Andes, Indonesia, the Himalaya, and Africa. In polar regions these conditions are more easily satisfied, so glaciers are extensive there.

Classification

Geographic Setting

Glaciers are classified according to their size, their topographic surroundings, and their thermal regime. Large, geographically unconstrained glaciers include ice sheets (larger than 50 000 km², of which there are two: the Antarctic and Greenland ice sheets), ice caps (smaller than 50 000 km²; e.g., Iceland), and ice shelves (e.g., Antarctica's Ross and Ronne ice shelves). Smaller glaciers that are typically confined by their topographic setting include mountain glaciers, outlet glaciers, icefields, valley glaciers, piedmont glaciers, cirque glaciers, hanging glaciers, and tidewater glaciers. Glaciers are also classified according to the climate regime in which they exist

(maritime, continental, or transitional, as determined by a combination of temperature and precipitation).

Excluding ice sheets and ice caps, the world's largest glacier is the Lambert glacier in east Antarctica, at approximately 100 km wide, 400 km long, and 2500 m thick. Outside of the polar regions, the largest glacier is the Fedchenko glacier in Tajikistan (77 km long). As part of the western Himalaya, the Karakoram is home to a number of the next largest glaciers, including the Siachen (70 km), the Biafo (63 km), and the Baltoro (62 km long).

Thermal Classification

The thermal regime of a glacier (i.e., its internal temperature structure) has important ramifications for how it moves. A glacier can be polar, in which case its temperature is everywhere below the freezing point (273.15 K), or it can be temperate, meaning that most of the ice is maintained at or near the pressure melting point through a combination of seasonal melting then refreezing of the meltwater as it percolates into the glacier (with the latent heat release during refreezing maintaining a higher temperature). Most glaciers in the Alps, for example, are temperate glaciers whereas high latitude glaciers are polar. There is also the possibility of a combination of these two thermal regimes, called polythermal glaciers, which exist in subpolar–polar Canada and Russia where geothermal heating from below raises the basal ice to the pressure melting point while the surface of the ice is maintained well below the freezing point.

Cumulatively, glaciers cover approximately 10% of the Earth's surface area, they contain about 75% of the world's freshwater and, if they were all to melt then global sea level would rise by approximately 70 m. Conversely, sea level was approximately 120 m below today's level during the peak of the last glacial cycle about 21 000 years ago when much of the water in the oceans today was locked up as terrestrial ice. The glaciers observed today are remnants leftover from that last glaciation which saw 30% of the Earth's surface area glacierized, with ice over 3 km thick covering central Canada. Glaciers are therefore intimately linked to global climate and fluctuate in concern with global temperatures, greenhouse gas concentrations and, going further back in Earth's history, continental configuration as plate tectonics move the continents around the Earth's surface.

Mass Balance

The mass balance of a glacier is an indicator of the health of a glacier and is a measure of the annual mean difference between accumulation and melt. A negative mass balance means the glacier is on average losing mass and, if the climate does not change, it will disappear. A positive mass balance means the glacier is growing in volume (though not necessarily in area). Mass balances of glaciers are not easy to quantify because the underlying topography (and hence ice thickness) is not easily measured. What is more easily measured are the processes occurring at the surface of a glacier, so a 'surface' mass balance, or 'climatic' mass balance is commonly used. These balances are calculated by an energy balance equation that

takes into account net shortwave and longwave fluxes, net accumulation, net melt, and net latent heat fluxes to determine if the surface is accumulating mass or losing mass to melt. If the surface mass balance is negative everywhere, it is likely that the glacier overall has a negative mass balance. Such studies have made use of both ground measurements and satellite observations for Greenland (e.g., Box et al., 2013) and Antarctica (e.g., Shepherd et al., 2012). Recently, the Gravity Recovery and Climate Experiment (GRACE) satellite data have been used to detect gravitational anomalies directly associated with volumetric ice mass gain or loss (see the previous two references). These methods work well for large ice sheets whose fluctuations have a measurable gravitational signal but for the world's extensive network of alpine glaciers, scientists must rely on either aircraft data or *in situ* measurements to obtain surface data (complicated by the fact that many alpine glaciers are not easily accessible and some are located in geopolitically sensitive areas).

Dynamics

Like rivers, ice flows under the constraints of gravity and the underlying topography. The timescale of flow depends on a number of factors including ice thickness and temperature, steepness of topography, atmospheric temperature, and the presence or absence of liquid water underneath the ice. Typical timescales for the flow of very large ice sheets is on the order of centuries to millennia whereas for smaller mountain or valley glaciers the timescales can be as rapid as decadal, annual, or even subannual. Some glaciers exhibit rapid surges through unique combinations of the factors listed above. The fastest observed glacier, the Jakobshavn glacier in Greenland, has varied in speed over the years but values range from 5.7 km per year in 1992 to 15 km per year in 2010 (roughly 41 m per day), a near tripling of speed over this period. This is a significant change considering that this glacier drains approximately 5% of Greenland ice into the ocean, thereby forming approximately 10% of Greenland's icebergs and raising sea level by approximately 4% of the measured twentieth century amount.

From a practical and numerical perspective, the flow of ice is mathematically treated using Glen's flow law, which is an empirically derived relationship between ice stress and the strain rate. The stress is in turn related to the ice density, thickness, and slope. It is greatest at the base of the glacier in contact with the bed, where ice deformation is greatest and the velocity slowest. It is smallest at the glacier surface, where deformation is smaller and velocities are greater.

Like rivers, glaciers flow downhill. Mountain and valley glaciers therefore flow into warmer temperatures at lower elevations (temperature in the free atmosphere decreases with elevation at a rate of between 2 and 9.8 °C km⁻¹). The glacier can therefore flow into climatic conditions not conducive to the presence of ice. Similarly, outlet glaciers flow into oceans or lakes where the ice calves off to form icebergs (e.g., the Perito Moreno glacier, Argentina; Figure 1).

A simplified picture of the evolution of a glacier is of mass accumulation at high elevations, ice dynamically flowing

Figure 1 The active Perito Moreno Glacier, southern Patagonia, Argentina. Photo A.B.G. Bush.

downhill to lower elevations where it melts (or calves off). The elevation at which net accumulation equals net loss is called the equilibrium line altitude (ELA). ELAs are therefore dependent on temperature and precipitation, so change with the regional (and global) climate, with ELAs in general being lower during glacial periods (on the order of hundreds of meters) and higher during warmer interglacial periods. If the ELA is physically higher than the surrounding topography then the existence of a glacier is precluded. The rise of ELAs due to global warming is therefore of concern for those glaciers that are near the top of their topographic environment.

Rheology

The dynamic behavior of ice depends on its rheology. Ice can behave as a brittle substance prone to fracturing if it is subjected to rapid stress, or it can behave as a viscous substance if the applied stress has a relatively slow timescale. The timescale separating these behaviors is the Maxwell time, which is determined by the ratio of the kinematic viscosity of ice (units of pressure–time) to the shear modulus of ice deformation (units of pressure). The Maxwell time for typical glacier viscosities (10^{13} Pa s) and shear moduli (3.5×10^9 Pa) is about 50 min. The viscosity, however, is temperature dependent so the Maxwell time is smaller for warmer glaciers (on the order of a few hours) and longer for colder glaciers (on the order of months or more). This fact plays a role in the numerical modeling of glaciers since the discrete time step chosen in models must be less than the Maxwell time in order to ensure numerical stability.

Fracturing by the former, brittle, behavior results in crevasses when the flow of the glacier is over topographic features or there is convergence/divergence with tributary glaciers or sidewalls (Figure 2). Crevasses can be transverse (across the direction of ice flow, resulting from divergence and extension of ice in the direction of flow); longitudinal (aligned with the direction of flow, resulting from cross-flow divergence usually from underlying topography); or chevron (at an angle with valley walls, caused by friction with topography). Rapid radial spreading of ice unconstrained by topography also produces crevasses.

Figure 2 Crevasse on the Godwin-Austen Glacier, at the base of K2. Photo A.B.G. Bush.

Topography and Glaciers

Climate-glacier dynamics are complicated given the coupling of climate, surface processes, and geological conditions and tectonics. A multitude of feedback mechanisms and forcings govern the response of glaciers to climate change. The topography underlying a glacier plays a critical role in its evolution.

The complexity is highlighted by the fact that the topography is the effective result of system couplings, such that energy and water input, erosion and deposition, and mass influx (uplift) and deformation govern the morphological characteristics of the topography. This in turn defines the magnitude of topographic properties such as altitude, slope angle and azimuth, curvature, relief, and regional topographic structure that partially govern the magnitude of numerous surface processes. Glacier processes are uniquely coupled with mass movement and fluvial processes, thereby resulting in extreme variability in glacier dynamics.

It is well known that orbital dynamics and radiative forcing resulted in glacial expansion in the past. Glaciers have tremendous ability to erode the landscape, as related to ice thickness and meltwater production. As lithospheric mass was removed in the past and the geological system responded via isostatic uplift, glacier dynamics and erosion resulted in the formation of deep U-shaped valleys, polished valley sidewalls, steep local slopes, regional relief production, and a reduction of local slopes at high altitude (Figure 3). Glaciers effectively eroded the landscape and left behind

Figure 3 Valley carved by a tributary glacier on the south side of the Baltoro Glacier, Pakistan. Photo M.P. Bishop.

high-altitude erosion surfaces when they retreated. These surfaces have been identified and mapped in numerous mountain environments.

The changing topographic parameters and structure played an important role in the changing evolution of the landscape. Various local and regional topographic parameters govern the magnitude of surface irradiance, which in turn governs the magnitude of evapotranspiration, ablation, and meltwater production. The magnitude of all three surface irradiance components, direct irradiance, diffuse-skylight irradiance, and adjacent-terrain irradiance, are governed by multiscale topographic parameters that dictate extreme spatiotemporal variability in surface irradiance. These topographic effects on individual glaciers and regional patterns of mass balance are not yet well understood. One of these effects, the adjacent-terrain component, is often responsible for the cross-sectional surface morphology of a glacier, as ablation is higher on the sides of a glacier depending upon ice proximity to adjacent surfaces, valley walls, and the azimuth of solar radiation.

The local and regional topographic structure influences the dominance of climate systems and the magnitude of precipitation, which also governs mass balance. The size and orientation of deep glacial valleys serves as a pathway for weather systems, governed by the global climate. For example, in the Himalaya, glacier valleys serve as a conduit for the seasonal monsoon system to penetrate deeper into the range such that annually, glacier systems may be effected by the westerlies and the monsoon. Furthermore, regional altitude variations and steeper slopes produce an orographic precipitation effect thereby influencing the magnitude of precipitation or snowfall. Such an orographic precipitation effect has been documented in the Karakoram of Himalaya, as a water mass anomaly and advancing glaciers highlight a unique topography-climate-glacier dynamic. This dynamic is also spatially coincident with a large number of recently identified surging glaciers, thought to be the result of mass loading (e.g., Scherler et al., 2011).

The topography also governs ice-flow dynamics and glacier surface characteristics. Glacier erosion is thought to scale with ice thickness and basal velocity, such that the slope angle and ice thickness governs the basal shear stress and

erosion potential. Although many other variables are involved, abrasion and the scouring and removal of rock and sediment that is redistributed along the base of the glacier are important. It becomes part of the bed load, and englacial load, and at the terminus of the glacier, may move upward as part of the englacial load to become part of the supraglacial load on the glacier surface. Rapid glacial incision lowers the valley and coupled with uplift, relief production reduces surface ablation over time, due to cast shadows and increased topographic shielding from solar radiation. Steep slopes and positive mass balance increases ice velocity thereby increasing erosion potential. Over time, erosion and redistribution of sediment may reduce slope angles and erosion potential, but this may be offset by ice thickness and meltwater production governed by surface conditions and climate change.

Glacier surface characteristics strongly control ablation and meltwater production. Most glaciers around the world are heavily debris covered (Figure 4). Depending upon the lithology/minerological composition of the debris and its depth, ablation may be significantly enhanced or reduced. Thin debris layers on a glacier surface enhance ablation and meltwater production, while thick debris layers protect the glacier from losing its mass. Debris depth variations over a glacier surface are highly variable and depend on local topography. Debris-covered glaciers are believed to be relatively insensitive to climate change. However, debris cover can vary significantly along a glacier, with more near the terminus and less at higher elevations. The general trend of debris-cover depth is one of the decreasing debris depth with increasing altitude. The terminus of a glacier usually exhibits the greatest debris depths. Measured debris depths can vary from ~0 to ~5 m. Debris can be highly variable from a lithological and particle size distribution perspective and include car-sized and house-sized boulders.

The adjacent topographic conditions regulate the magnitude of supraglacial debris loads. Snow avalanches, landslides, rock falls, and other mass movement processes dictate the quantity of debris that makes its way onto the glacier surface. As the ice flows down the valley there is a build-up of debris depth, such that it is relatively high near the terminus. In general, this is facilitated with relatively high surface velocities

Figure 4 Debris-covered terminus and outflow of the Baltoro Glacier, Pakistan. Photo M.P. Bishop.

and a systematic decrease toward the terminus. Consequently, as the debris builds up over time, and as the glacier is actively moving downhill, sediment transport is facilitated, and there is a feedback between the cohesive nature of the sediment, the slope of the sediment surface, and the sediment discharge per unit area. So in addition to the ice topographic conditions, the sediment topographic conditions also regulate surface irradiance and ablation.

The aforementioned dynamics are initially controlled by regional topographic conditions related to topographic stress tectonism, and climate. Given the paleoclimatic and glacial chronological conditions that have sculpted the surrounding topography, the three-dimensional topographic stress field strongly influences rock strength and slope-failure potential. Consequently, valley-wall slope failures and landslides contribute to the debris load. Active tectonics and earthquakes also generate material, and there may be considerable variation in supraglacial debris characteristics given variations in the topographic and geological setting. High magnitude glacier erosion and uplift is known to generate relief and therefore can enhance debris production.

Glacier surface topography and debris-load variability governs meltwater production and distribution of water, such that supraglacial runoff and streams are common on many glaciers (Figure 5). Surface water may flow into crevasses and moulins to become part of the englacial conduit network, or make its way to the base of the glacier (Figure 6). Frequently, supraglacial runoff accumulates in local topographic depressions thereby forming a supraglacial lake that can drain englacially or subglacially (Figure 7). Differential ablation or rapidly expanding supraglacial lakes can result in the formation of ice cliffs (Figure 8) that are usually characterized by steep slopes and a thin moisture-laden debris layer that dramatically enhances ablation and meltwater production. Many supraglacial lakes are found adjacent to ice cliffs resulting from rapid melting of ice along the ice-cliff surface. The presence of such numerous and complex surface feedbacks that rapidly change the glacier surface warrants further investigation regarding the sensitivity of debris-covered glaciers, and the role of topography in glacier dynamics.

Glacier–Climate Interactions

In general, and in the absence of debris cover, glaciers have a relatively high albedo compared to their surroundings so they reflect a large fraction of solar radiation. The positive ice-albedo feedback can promote glacier growth (if a glacier grows in area it reflects more solar radiation thereby cooling atmospheric temperatures and promoting further growth) or it can promote glacier demise (if a glacier shrinks in area it reflects less solar radiation thereby warming the atmosphere and promoting further shrinkage). The albedo of a glacier is, however, not straightforward. The presence of surface meltwater, new snow, old snow, rock debris, black soot can change the surface albedo and hence the radiation budget at the surface. Rock debris cover, for example, can protect a glacier from melting if the coverage is sufficiently deep that the ice is no longer in direct contact with the atmosphere. Sparse and scattered debris cover, on the other hand, enhances surface melting because the rocks heat under insolation and melt into the ice. The presence of meltwater ponds on a glacier surface dramatically decreases the albedo and enhances melting during the ablation season.

The fact that 10% of Earth's surface is glacierized means that Earth's globally averaged albedo is higher than it would be if there were no glaciers. Earth's global mean temperature is therefore lower than it would be with no ice. Glaciers not only respond to changes in global climate, they also contribute to that climate through atmosphere–ice interactions.

Global Glaciations

There is geologic evidence for glacial periods as far back as the Precambrian era, approximately 2900 Ma. The multiple Snowball Earth events of the Neoproterozoic period may have created global glaciation (continental and marine; e.g., Hoffman and Schrag, 2002). Less extensive glacial events are known to have occurred during the late Ordovician/early Silurian (~430 Ma), the Carboniferous/Permian transition (~280 Ma), and, more recently, the past 2 million years of the Pleistocene.

When looking at glaciations during such deep geological time periods there are many factors that must be taken into account. One is continental configuration; the presence of land mass near the poles is more likely to produce glaciation. For example, the glacial scarring of rocks that provides evidence for the Ordovician glaciations exists in what is now the Sahara Desert but at that time the African plate was situated near the south pole. Another factor is solar luminosity, which slowly increases with time (e.g., luminosity during the Ordovician was approximately 3% lower than it is today).

The third factor is greenhouse gas concentration in the atmosphere. Changes in carbon dioxide over geologic time-scales (tens of millions of years) is a natural cycle involving volcanism and atmosphere–ocean interactions (e.g., during the Ordovician atmospheric carbon dioxide is believed to have been 10–15 times the preindustrial value). Greenhouse gases play a key role in determining the longwave flux into the surface of a glacier and hence influence the energy balance at the surface. All else being equal, higher greenhouse gas concentrations provide more energy available to melt ice.

There is much more proxy data available to study the recent Pleistocene glaciations, which began during a period of global cooling, and that is simply because glaciations tend to eradicate evidence of previous glaciations through their transformation of the landscape (where proxy data are collected). Earth's orbital parameters of obliquity, eccentricity, and precession have played a key role in modulating glaciations for the past 2 million years. During the early Pleistocene, reconstructions from oxygen isotope data from the seafloor indicate a ~41 000-year cycle of glaciations, indicating that changes in Earth's obliquity modulated glacial cycles. During the midlate Pleistocene, however, glaciations switched to a ~100 000-year cycle, indicating that the eccentricity of Earth's orbit became the dominant factor. Why the timing of glaciations switched periods is still an outstanding question, as is the fact that the 100 000-year eccentricity cycle is radiatively quite weak yet the last nine glacial cycles have been on this period.

Current Climate and Glacier Status

Given the importance of glaciers to climate and to freshwater resources around the globe, monitoring efforts have been underway for decades. The past few decades of global warming have been reflected in the near worldwide retreat of glaciers, particularly the humid-maritime glaciers of Western Canada, Alaska, and Patagonia (e.g., Solomon et al., 2007). In the Arctic, for example, virtually all monitored glaciers lost mass

(one exception being Svalbard) with the greatest loss occurring in the most recent years (Sharp et al., 2012).

Projections for the future fate of glaciers around the world rely not only on *in situ* observations, but also on numerical models that simulate the climate under various greenhouse gas forcing scenarios (e.g., Janes and Bush, 2012; Marshall et al., 2011; Pollock and Bush, 2012). As an example, the Canadian Rockies are projected to lose up to 80–90% of ice volume by the end of the century (Marshall et al., 2011). The Himalaya, dubbed ‘the third pole’ given its number of glaciers and their size, also shows trends of negative mass balance in the central and eastern parts of that range. However, according to observations one exceptional region appears to be the Karakoram, which has a number of stable or even advancing glaciers (Scherler et al., 2011). Nevertheless, modeling projections indicate that by the end of the century, even the glaciers in this anomalous region will only be able to exist at the highest elevations (Janes and Bush, 2012).

There is still much work to be done on glaciers in terms of mass balance, the streamflow that they produce, the erosional characteristics that they exhibit, the biogeochemical nature of subglacial waters, and ultimately their evolving impact on humans and our freshwater resources.

Introduction

Permafrost, ground that remains at or below 0 °C for two or more years, underlies about a fifth of the land surface of the Earth. Permafrost terrain consists of an active layer at the surface that freezes and thaws each year, underlain by perennially frozen ground. The top of permafrost is at the base of the active layer, and the base of permafrost occurs where the ground temperature rises above 0 °C at depth (**Figure 1**).

The first scientific reports on permafrost were published in the 1830s by the Royal Geographical Society of London. These papers reported the thickness of frozen ground in a well at Yakutsk, Russia, and provided instructions to officers of the Hudson's Bay Company on describing the phenomenon. The first systematic study published in English of perennially frozen ground was prompted by strategic considerations in World War II, when the Alaska Highway was built through northern British Columbia and Yukon to Alaska, with the associated Canol

Pipeline. At that time, the term 'permafrost' was coined by S. W. Müller as a contraction of 'permanent frost'.

Permafrost grows by freezing from its base downward or, when new material is added to the ground surface, from the top upwards, or by a combination of these processes. The first permafrost on Earth likely formed prior to or during the first ice age about 2.3 billion years ago, and its occurrence, distribution, and thicknesses have varied in response to repeated ice ages throughout Earth's history.

There is scientific and geotechnical interest in permafrost principally because it contains ice, is close to its thawing point, and is sensitive to changes in surface conditions caused by human activities and climate. Temperatures in permafrost present retrievable records of past climate, and climatic change commonly leaves an imprint on the stratigraphy of ground ice. Ice-rich permafrost contains ice in excess of the water content at saturation, with the ice masses commonly distributed as lenses, millimeters to centimeters in thickness, within the ground. Massive ground ice with dimensions typically from meters to tens of meters also occurs in permafrost (**Figure 2**).

Figure 1 Schematic temperature profiles in permafrost, illustrating the annual maximum and minimum temperatures. Annual mean permafrost surface temperature, T_{ps} , is obtained by extrapolating the common linear portion of the profiles upwards. Soil particle effects, solutes, and hydrostatic pressure decrease the phase equilibrium temperature so that a layer just above the base of the permafrost does not contain ice. The change in slope of the temperature profile at the base of ice-bearing permafrost is caused by the difference in thermal conductivities between the frozen and unfrozen ground.

Occurrence, Distribution, and Thickness

The spatial extent of permafrost generally changes with climate, but there can be considerable regional variation because of snow cover and other factors. Over half of Canada and Russia, most of Alaska, and north-east China are underlain by continental permafrost, while alpine permafrost is found at high elevations in middle and low latitudes (e.g., the summit of Mauna Kea in Hawaii). Some permafrost is found in Scandinavia, but the spatial extent is much less than at corresponding latitudes of North America, because of the warming influence of the Gulf Stream. Permafrost containing water ice and other ices is known to exist on Mars and on other bodies in our solar system.

Permafrost regions are divided into zones with varying spatial extent of perennially frozen ground. In the continuous permafrost zone (**Figure 3**), more than 90% of the ground is underlain by permafrost, and it is usually absent only beneath rivers and lakes that do not freeze to their bottom in winter. At continental scale, the limiting annual mean air isotherm for continuous permafrost is about -8°C . At warmer temperatures, variations due to microclimatic effects lead to a zone of widespread discontinuous permafrost where 50 to 90% of the ground is underlain by permafrost. In the sporadic discontinuous permafrost zone, 10 to 50% of the ground is underlain by permafrost.

Subsea permafrost formed during glacial periods, when lower sea levels exposed large areas of the polar continental shelves. The cold air temperatures and long periods of exposure allowed permafrost to grow there to great depths.

Figure 2 Massive ground ice exposed at the Beaufort Sea coast near Tuktoyaktuk, Northwest Territories. The ice was formed during permafrost aggradation after deglaciation, with water supplied from the underlying sands. Banding indicates variations in the concentration of sediment suspended in the ice. Undulation of the banding indicates displacement of the ice subsequent to formation. Photograph by J. R. Mackay. See Mackay JR and Dallimore SR (1992) Massive ice of the Tuktoyaktuk area, western Arctic coast, Canada. *Canadian Journal of Earth Sciences* 29: 1235–1249.

Thicknesses of several hundreds of meters are known to exist in these shelves and, at present, this permafrost is slowly degrading beneath the relatively warm and salty ocean. However, several tens of thousands of years are required to thaw it completely.

The distribution and thickness of permafrost are controlled by factors that influence its heat balance and heat flow within it. Since pore spaces in permafrost are generally blocked by ice, heat flow is by conduction. While the presence of permafrost is due primarily to climate, considerable modification of the temperature between the atmosphere and permafrost may occur, owing to vegetation, energy exchanges at the snow-ground surface, transfer of heat through the active layer, and local geological and hydrological conditions. In particular, the winter snow cover buffers the ground from frigid air temperatures, and the annual mean ground surface temperature, T_s , is commonly 2 to 4 °C warmer than the annual mean air temperature, T_a . In the summer months, shade from vegetation and a supply of soil moisture for evaporation are two significant site variables that reduce the ground surface temperature. T_a and T_s tend to be similar at windswept sites where there is little snow accumulation. Significant changes in ground temperatures occur across the continental tree line, for within the forest there is less wind at ground level than on the tundra, and hence the snow is deeper, less dense, and a better insulator.

An organic horizon at the ground surface commonly assists the development and persistence of permafrost. Dry moss and peat have low thermal conductivities, reducing heat flow into the ground in summer. However, autumn rain characteristically increases the water content of the moss and peat, increasing their conductivity (particularly when frozen) and facilitating

Figure 3 Generalized map of the approximate distribution of permafrost in the north circumpolar region of the Earth. Direct data (probing, drilling, sampling, temperature measurements) are scarce, so the map is somewhat unreliable, especially at local scales in discontinuous permafrost. Subsea permafrost typically exists in the continental shelves of the Arctic Ocean where seabed temperatures remain negative. Adapted from Péwé TL (1983) Alpine permafrost in the contiguous United States: a review. *Arctic and Alpine Research* 15: 145–156, by permission of the Regents of the University of Colorado.

extraction of heat from the ground in winter. These principles indicate why, near the southerly limit for continental permafrost in North America, permafrost generally occurs in peat lands and under thick moss layers.

At regional scale, permafrost distribution may be controlled by topography, in terms both of aspect, modifying the receipt of radiation, and of cold conditions brought by high elevation. However, in the mountain and plateau regions of Alaska and adjacent Canada, strengthening of winter inversions by cold-air drainage into valley bottoms enhances conditions for permafrost there.

The thickness of permafrost is commonly influenced by geothermal heat flow and bedrock stratigraphy. At continental scale, heat flow varies by a factor of four between stable craton, where the flow is low, and tectonically active terranes. This geothermal heat is conducted through the permafrost where the temperature gradient varies with the thermal conductivity of the bedrock. At local and regional scales, the movement of groundwater carries heat that can modify the spatial distribution and thickness of permafrost. Under equilibrium conditions where a constant annual mean permafrost surface temperature, T_{ps} , has existed for a long time, the thickness of homogeneous permafrost, Z_e , is governed by T_{ps} , the thermal conductivity of permafrost, K_p , and the geothermal heat flow, J , where (from Fourier's law)

$$Z_e \approx \frac{K_p}{J} T_{ps} \quad [1]$$

Equation [1] provides reasonable estimates of Z_e when T_{ps} remains near its long-term value or has been close to it for a sufficient period. While T_a is the principal variable governing T_{ps} , the values differ owing to the effects of snow cover, the active layer, and other factors mentioned above.

Properties and Processes

Unfrozen Water and Ice

Seasonally frozen ground and permafrost contain unfrozen water (Figure 4) and ice in equilibrium at temperatures less than 0 °C as a result of the effects of soil particles and solutes. In the absence of solutes, temperature, T , and the soil's specific surface area, S , are the primary determinants of the amount of unfrozen water, θ_u , and are empirically related by

$$\ln \theta_u = 0.2618 + 0.5519 \ln S - 1.449S^{-0.264} \ln |T| \quad [2]$$

where θ_u is in percent. Unfrozen water reduces ground thermal conductivity and distributes latent heat over a range of temperatures, so that temperature changes require freezing or thawing throughout the frozen ground. These effects retard the thermal response of the active layer and permafrost.

Frost Heave

Unfrozen water is also responsible for the development of ice lenses in the ground during freezing, leading to local uplift (heave) of the surface. The water occurs in mobile films on particle surfaces, where it is held in tension. Water flows along the tension and thermal gradients in the films to cooler regions

Figure 4 Representative values for the temperature dependence of unfrozen water contents in sand, silt, and clay. Unfrozen water contents typically increase with temperature and finer-grained soil and are small in moss and peat. The presence of solutes increases unfrozen water contents.

of the ground. When the water content in the freezing soil exceeds saturation, the excess volume separates soil particles to form layers, or lenses, of segregated ice. Ice segregation and frost heave characteristically occur in fine-grained soils, where the unfrozen water content is sufficiently large to conduct water into the freezing ground. In coarse-grained soil, the unfrozen water content is small and the permeability is too low to allow water migration during freezing. In saturated, coarse-grained soil, the expansion of water during freezing is accommodated by expelling the excess water into unfrozen ground ahead of the freezing front. When the freezing system is closed, pore-water expulsion may also lead to heave as hydrostatic pressure deforms the overlying frozen ground.

Active Layer

Permafrost is separated from the atmosphere by a boundary layer consisting of the active layer and vegetation in summer with the snow cover added in winter. The active layer transmits heat to and from permafrost, reduces the amplitude of thermal variations at the top of permafrost compared with the ground surface, is the medium through which moisture and gases are exchanged between the permafrost and the atmosphere, and provides water and nutrients for biological processes. In permafrost terrain, the active layer supports plant and animal communities since virtually all biological activity below ground occurs within it.

Permafrost immediately below the active layer is characteristically ice-rich. This ice-rich zone acts as an impermeable barrier to drainage, so much permafrost terrain is wet. The ice-rich zone is the reason permafrost terrain is considered sensitive to disturbance, for deepening of the active layer commonly leads to subsidence (thaw settlement) and accelerated erosion as the ice melts.

In a dry active layer, $T_s \approx T_{ps}$; however, in a wet one, there is an asymmetry in heat flow because the frozen thermal conductivity, K_f , exceeds K_t , the thawed conductivity. This makes T_s warmer than T_{ps} and the difference is the thermal offset (Figure 5)

$$T_{ps} - T_s = \frac{I_t}{P} \left(\frac{K_t}{K_f} - 1 \right) \quad [3]$$

where I_t is the thawing index at the ground surface and P is the period (365 days).

Once the snow melts, the ground surface warms above 0°C and thawing of the active layer begins (Figure 6). In a simplified model, its maximum thickness is

$$X \approx \sqrt{\frac{2K_t I_t}{h}} \quad [4]$$

Figure 5 Annual mean temperature profiles in the active layer showing the effects of thermal offset. In the context of climatic change, thermal offset allows permafrost to survive changes that produce annual mean ground surface temperatures warmer than 0°C over multiyear periods as shown at this site. Adapted with permission from Osterkamp TE and Romanovsky VE (1999) Evidence for warming and thawing of discontinuous permafrost in Alaska. *Permafrost and Periglacial Processes* 10: 17–37.

where h is the volumetric latent heat of the ground, which depends on the ice content. The thickest active layers (1 to 2 m or more) develop in dry materials, characteristically bedrock, sand, and gravel. Thin active layers are common in wet organic soils, where there may be considerable amounts of ice at the beginning of summer, and where the thermal conductivity of a dry surface layer is very low. The thinnest active layers, less than 30 cm thick, occur in the High Arctic, owing to short, cool summers.

The active layer typically reaches X and begins freezing upward from the bottom when $T_s > 0^\circ\text{C}$, one or two weeks before freezing downward from the surface. Temperature changes during freezing are retarded by the presence of unfrozen water for a few weeks in cold permafrost and for much of the winter in warm permafrost. The rate of freezing down from the surface depends on the amount and timing of the early winter snow cover and on the thermal conductivity and moisture content of the active layer. Freezing may be slow if a deep snow cover is established early in winter on a wet active layer. Temperatures in the portion of the active layer that remain thawed are constrained near 0°C , a phenomenon termed the ‘zero curtain’, until freezing is complete.

Thermal Regime

A temperature profile in permafrost that is homogeneous, does not contain unfrozen water, and is in equilibrium with a constant long-term T_{ps} , is a straight line described by Fourier’s law (seasonal variations near the surface and freezing point depression near the base cause deviations from a straight line). However, the thermal regime of permafrost is often characteristically different during its formation and growth, after surface temperatures change, and during thawing. Prior to permafrost formation, interannual variability in T_s and in conditions within the seasonally frozen layer can cause the depth of freezing to exceed the depth of thawing during the following summer, resulting in a temporary layer of frozen ground. T_s can be significantly positive when this occurs, owing to thermal offset. A long-term shift in conditions allows such a layer to persist and grow, creating a thickening layer of permafrost with time. When the permafrost freezes from its base downward, the solution of the Stefan problem yields the approximate depth to the bottom of the growing permafrost at time t :

$$Z \approx \sqrt{\frac{2K_p (-T_{ps})t}{h}} \quad [5]$$

In eqn [5], K_p and h depend on ground properties. Equation [5] neglects geothermal heat flow and the effects of freezing point depression near the base of permafrost (Figure 1). It reduces to $Z \approx \text{constant} \cdot \sqrt{t}$, where the constant is typically about 1 to 5 for a wide range of conditions, where t is measured in years and Z in meters.

In principle, permafrost grows until $Z = Z_e$, when it is in equilibrium with T_{ps} . However, in reality, T_{ps} is variable over the long time scales needed to grow even relatively thin permafrost, resulting in permafrost thicknesses that vary with long-term variations in T_{ps} (Figure 7).

A change in T_{ps} (warming or cooling) produces a curvature in the temperature profile that penetrates deeper with time (Figure 8). The magnitude of the change at any depth can be

Figure 6 Time series of temperatures at the ground and permafrost surfaces for the annual cycle. Freezing of the active layer from the top downward began about 26 September 1987, and from the bottom upward about ten days earlier. The zero curtain persisted until about 12 November 1987, the date of freeze-up of the active layer. At this time, the lower portion of the active layer and upper portion of the permafrost began to cool. Ground surface temperatures during spring, 1988, remained near 0 °C from 4 to 11 June (the period of snowmelt), when the active layer began to thaw.

Figure 7 Calculated permafrost thickness variations in response to changes in paleoclimate. Thicknesses varied about 84 m ($562 \text{ m} \leq Z \leq 646 \text{ m}$) with maximum thawing rates of 5 mm yr^{-1} and freezing rates of 2 to 3 mm yr^{-1} . Adapted with permission from Osterkamp TE and Gosink JP (1991) Variations in permafrost thickness in response to changes in paleoclimate. *Journal of Geophysical Research* 96: 4423–4434. Copyright © by the American Geophysical Union.

Figure 8 Schematic thermal response of permafrost to warming of its surface temperature. Seasonal variations near the surface are not shown. The magnitude of the warming at any depth can be obtained directly from the measurements and the timing of the warming can be calculated from the depth of penetration of the warming signal. Adapted with permission from Lachenbruch AH, Sass JH, Marshall BV, and Moses TH (1982) Permafrost, heat flow, and the geothermal regime at Prudhoe Bay, Alaska. *Journal of Geophysical Research* 87: 9301–9316. Copyright © by the American Geophysical Union.

obtained from the measurements and the timing can be calculated from the maximum depth of penetration of the thermal signal. For permafrost with thickness Z , the time scale required for the temperature profile to respond to a new surface condition is

$$\tau \approx \frac{Z^2}{4D} \quad [6]$$

where D is the thermal diffusivity of the permafrost. Freezing or thawing at the bottom of the permafrost begins once the thermal disturbance has penetrated there, with calculated rates in thick continuous permafrost that are typically millimeters per year (Figure 7).

When $T_{ps} \approx 0^\circ\text{C}$, interannual variability in T_s and conditions within the active layer may cause the depth of summer thaw to exceed the depth of winter freezing, resulting in a temporary residual thaw layer between seasonally frozen ground and permafrost. T_s can be significantly positive when this occurs, and interannual variability may allow the layer to refreeze and thaw repeatedly. If the conditions that caused the warming persist, the layer may become too thick to refreeze. Then, the permafrost is decoupled from the atmosphere and warms continuously throughout the year. An equation similar to [5] can be obtained for the thickness of the thawed layer

above permafrost. Thawing rates at the top of the permafrost depend on the temperatures at the bottom of the former active layer, K_v and h and can be a few tenths of a meter per year for near-surface permafrost. While the permafrost is thawing, temperatures within it warm very slowly as they approach 0°C (Figure 9) because of the effects of unfrozen water.

Geomorphic Features

There are three principal geomorphic features unique to permafrost terrain: pingos (conical ice-cored hills) and ice-wedge polygons, both associated with permafrost aggradation; and thermokarst terrain, associated with ground thawing. Pingos may form in the unfrozen sandy sediments of drained-lake bottoms that are completely surrounded by permafrost. After drainage, lake sediments freeze primarily from the top downward and from the sides and bottom of the talik (the unfrozen layer) inward. Freezing of the sands results in pore-water expulsion into the enclosed talik, increasing hydrostatic pressure there. The increased pressure lifts the permafrost, and the water freezes in place, to create a core of ice in the mound (Figure 10). Pingos grow until the talik freezes completely. There are 1350 pingos in Canada's western Arctic, and the largest, Ibyuk Pingo, is 50 m high, over 1200 years old, and is

Figure 9 Temperature profiles in thawing permafrost near Fairbanks, Alaska obtained 9 years apart. The presence of unfrozen water retards temperature changes and produces the observed curvature below 8 m depth. growing about 2 cm taller annually. Pingos are also found at the base of hill slopes, where the pressure to lift permafrost may be provided by confined groundwater flowing down slope.

Ice-wedge polygons are ubiquitous in continuous permafrost terrain, where cracks occur in the permafrost as a result of thermal contraction in winter. The cracks relieve thermal stress approximately normal to their axes, yielding a polygonal network that may subdivide further as more cracks form. Ice wedges begin to grow in the cracks when spring snowmelt infiltrates them and freezes to form near-vertical sheets of ice. Repetition of the process over many years leads to development of wedges of ice, which commonly extend downwards from the base of the active layer for about 4 m (Figure 11), although some exceed 10 m in depth. Polygons are clearly expressed in lowlands, but movement of the active layer commonly obscures them on hill slopes. Ice-wedge growth deforms the surrounding ground to accommodate the additional volume. Growth of the ice wedges often forces the adjacent ground upwards and laterally, creating a trough above the ice wedge.

Warming or disturbance to permafrost terrain usually leads to deepening of the active layer and thawing of the ice-rich zone at the top of permafrost or of near-surface massive ground ice, causing local subsidence. This thaw settlement produces a pitted relief, called thermokarst terrain. Drainage conditions determine whether standing water will be present or not. When depressions in thermokarst terrain collect water, the disturbance to permafrost is enhanced, leading to growth of thermokarst lakes. ‘Beaded’ streams occur when a series of pools (beads) form along the stream as a result of thawing ice-rich permafrost or large ice masses. Most features of thermokarst terrain range from 1 to 100 m in lateral dimensions, although thermokarst lakes are often larger. Thermokarst depressions up to 100 km² in area and 5 to 20 m in depth form part of the landscape of Siberia, where they are called ‘alasses’.

Thermokarst terrain also includes retrogressive thaw slumps (Figure 12) that commonly develop where ice-rich permafrost is exposed by erosion in riverbanks, lakeshores, and along the coast, or by other processes. These features, with a near-vertical

Figure 12 Headwall of a retrogressive thaw slump in ice-rich glaciolacustrine sediments near Mayo, Yukon Territory, Canada. Lenses of segregated ice give the exposure its texture. The ice lenses developed when permafrost formed in glacial lake sediments after drainage of the lake at the end of the last glaciation. A deep active layer, which formed during the warmest climate of the last 10 000 years, left a thaw unconformity in the sediments marked by the abrupt transition between the darker, lower, ice-rich material, and the lighter sediment above. Photograph by C. R. Burn. See Burn CR (2000) The thermal regime of a retrogressive thaw slump near Mayo, Yukon Territory. *Canadian Journal of Earth Sciences* 37: 967–981.

retreating headwall and a low-angled foot slope, are the commonest form of landslide in permafrost terrain. Landslides involving only the thawing active layer also occur, particularly in areas of fine-grained, ice-rich soil, when the active layer and vegetation detach from the underlying frozen material. If ice-rich permafrost or massive ground ice is exposed, the slope failure may develop into a thaw slump.

Impacts of Climatic Warming

The Earth's climate has generally warmed since the mid-to late 1800s. In the Arctic and Sub-Arctic, permafrost has also warmed, particularly in Russia, China, Mongolia, Alaska, and western Canada. In Alaska, T_{ps} for continuous permafrost warmed 2 to 4 °C over the last century followed by a cooling in the early 1980s and then a warming of up to 3 °C since then. In central Alaska and the Yukon Territory of Canada, discontinuous permafrost has warmed since 1970 as a result of changes in air temperatures and snow cover. While it has warmed typically 1 to 2 °C since the late 1980s in Alaska, the ground has been cooling in the Yukon owing to a reduction in snow cover. In the Northwest Territories, warming of permafrost by about 1 °C has been observed since the early 1970s, but in northern Québec there has been cooling. Such regional variations are to be expected as a result of spatial climatic variability. However, the general signal from the Northern Hemisphere indicates permafrost warming, and in some areas permafrost is presently thawing at both top and bottom, the southern boundary of the permafrost is moving northward, and the occurrence of thermokarst terrain is increasing.

Current global circulation models predict that air temperatures in the Arctic will rise 2 to 5 °C during the next half-century,

with the warming in winter larger than in summer and with more precipitation throughout the year. While there is considerable uncertainty in these predictions, warming of T_{ps} by a few degrees would have serious consequences for permafrost regions, especially for discontinuous and sporadic discontinuous permafrost.

In the continuous zone, the active layer, thaw lakes, coastal processes, landscape processes, eolian activity, and vegetation would be sensitive to climatic warming. The effect on the permafrost would be to warm it and, possibly, to change the depth of the active layer. Thawing at the base of the permafrost would start several centuries or more later.

Since most of the discontinuous and sporadic discontinuous permafrost is within a few degrees of thawing, it can be expected to warm, to begin thawing from the top and bottom with an increase in the incidence of thermokarst terrain, and, eventually, to disappear. Although many centuries would be required for the permafrost to disappear, thawing of the warmest permafrost from the top would begin immediately.

Thawing of permafrost as a consequence of human activities and as a result of the climatic warming since the late 1800s serves as a model for what may be expected to occur with additional climatic warming. Where permafrost contains massive ground ice or is ice-rich, extensive differential thaw settlement has occurred, with damage to the natural terrain and to infrastructure. Human-induced thaw settlement is at present responsible for damage to infrastructure on permafrost where the built structures have raised ground temperatures above 0 °C (Figure 13). The magnitude of the thaw settlement is typically 1 to 3 m, but can exceed 5 m (vertical settling) of the ground surface. Repair of the infrastructure is costly and some structures, airports, and roads have been abandoned.

Figure 13 Longitudinal cracks in a road embankment near Fairbanks, Alaska. Snow removal during winter produces a berm along the shoulder and slope of the embankment that warms the underlying ice-rich permafrost, causing it to thaw and settle. Settlement under the shoulder and slope causes the edge of the embankment to tilt outward, putting the top surface of the embankment in tension, which eventually results in cracks. Patches (darker asphalt) in the pavement are a result of two long cracks and the guardrail on the far side of the road has sagged as a result of the thaw settlement. Photograph by T. E. Osterkamp.

Carbon and Trace Gases

Soils in northern regions may contain one-quarter to one-third of the Earth's total soil carbon pool, with much of it stored in frozen peat in near-surface permafrost. When permafrost thaws, the carbon is cycled through terrestrial ecosystems with the gaseous end products (CO_2 and CH_4) emitted to the atmosphere. While the details of this process are not well understood and are subject to environmental constraints, there is evidence that tundra regions may have shifted from being a carbon sink to a carbon source.

Gas Hydrates

Temperature and pressure conditions within and under thick permafrost are favorable for the formation and existence of gas hydrates that are a potentially abundant source of energy. Warming of the permafrost would eventually destabilize these hydrates, producing large quantities of gas (primarily CH_4) that may find its way into the atmosphere. Long time scales (many centuries or millennia) are required for this process. However, subsea permafrost in the continental shelves of the Arctic Ocean that was submerged and warmed by seawater more than a few thousand years ago could be emitting methane at present. Currently, there is too little information to adequately assess this problem.

Ecosystems

In areas of ice-rich permafrost, thaw settlement and development of thermokarst terrain destroys the substrate on which the current ecosystems rest, dramatically changing the nature of the ecosystems. The effects have been observed to include:

1. Destruction of trees and reduction in area of boreal forest ecosystems.
2. Expansion of thaw lakes, grasslands, and wetlands.
3. Destruction of habitat for caribou and terrestrial birds and mammals.
4. Formation of new habitat for aquatic birds and mammals.
5. Coastal and riverbank erosion.
6. Clogging of salmon spawning streams with sediment and debris.
7. Slope instabilities, thaw slumps, landslides, and erosion.
8. Talik development, with increasing depth to water table.
9. Increased methane emissions in wet areas.

Thermokarst has been observed to result in the partial or complete destruction of some ecosystems and their conversion to other types of ecosystems. In one lowland area in central Alaska, permafrost degradation is widespread and rapid, causing large shifts in ecosystems from birch forests to fens and bogs (Figure 14). If current conditions persist, the remaining birch forests will be eliminated by the end of the twenty-first century.

Synopsis

Sea ice is any form of ice found at sea that originated from the freezing of seawater. It is the most visible feature of the polar seas, with its extent waxing and waning with the seasons. Ice thickness is highly variable, ranging from a thin veneer to tens of meters. While the existence of sea ice reflects the cold conditions inherent to high latitudes, sea ice also strongly modulates the energy budget and climate of the polar seas and beyond, particularly because of its high albedo and through acting as a lid, insulating the underlying ocean from a generally much colder atmosphere. Sea ice extent and thickness are in turn influenced by changing climate conditions. Arctic sea ice extent and thickness as observed at the end of the melt season have declined significantly over the past several decades. In contrast, Antarctic sea ice extent has expanded slightly.

The Seasonal Cycle of Sea Ice

Ice Extent

Sea ice in the Northern Hemisphere attains its maximum seasonal extent in March and its minimum seasonal extent in September. At maximum extent, it can cover more than 15×10^6 km², somewhat less than twice the size of the contiguous United States. It covers essentially all of the Arctic Ocean and extends down the western side of the major ocean basins, paralleling the pattern of cold ocean currents, and reaching the Gulf of St. Lawrence (Atlantic Ocean) and the Sea of Okhotsk (Pacific Ocean). The most southerly site in the Northern Hemisphere where an extensive cover sometimes forms is the Bohai Sea, located off the east coast of China at 40°N. At the seasonal minimum, sea ice is largely confined to the central Arctic Ocean, with extensions into the Canadian Arctic Archipelago and along the east coast of Greenland. Through the 1970s and 1980s, September ice extent averaged around 7.0×10^6 km². As assessed over the period of satellite observations (late 1978 to present), there are downward linear trends in sea ice extent for all months; they are largest for September and smallest during winter. As of this writing, September 2012 held the record for the lowest ice extent in the satellite record, with a monthly average of 3.61×10^6 km². In satellite-derived sea ice maps, extent is generally defined as the region covered by ice with a concentration (fractional ice cover) of at least 15%. **Figure 1** illustrates seasonal contrasts in the coverage of sea ice for the Northern Hemisphere, using 2012 as an example.

The seasonal cycle of ice extent in the Southern Hemisphere is, of course, broadly opposite to that of the Northern Hemisphere, varying between about 3×10^6 km² in March and 20×10^6 km² in September (**Figure 2**). The larger seasonal range in ice extent for the Southern Hemisphere reflects differences in the spatial distributions of land and ocean. The Arctic Ocean is in large part landlocked, with only one major exit for sea ice: Fram Strait, located between Greenland and Svalbard. This constrains the maximum possible winter extent. The Southern Ocean is by comparison essentially unbounded

to the north, which allows unrestricted drift of the ice in that direction and results in the summertime melting of nearly all of the previous season's growth. In sharp contrast to the Arctic, Antarctic sea ice extent as a whole has remained fairly stable over the period of satellite observations and indeed has expanded slightly, with downward trends in some areas offset by positive trends in others. Extent in 2012 was the highest over the period of satellite coverage, acting as a counterpoint to the record low in the Northern Hemisphere. The significance of this record high for Antarctica, and of the record 2012 low for the Arctic, is quite different, however. As assessed over the period of satellite coverage, the steepest Arctic ice extent trend, for September, is $-13.0 \pm 2.9\%$ (relative to the mean over the period 1979–2000). Arctic ice for September 2012 was about 50% below its 1979–2000 average. For March, the trend in extent is $-2.6 \pm 0.6\%$. In contrast, the Antarctic ice extent trend is insignificant for March at 3.2% ($\pm 4.1\%$), while that for September is barely significant at 0.9% ($\pm 0.6\%$). Antarctic sea ice in September 2012, while at a record high, was less than 5% above its 1979–2000 average.

Surface Characteristics

Seasonal changes in ice extent are accompanied by pronounced changes in surface characteristics. As the polar night descends, any ice that survived the summer melt season, as well as new ice that forms in areas of open water, becomes covered with snow. As will be outlined in this article, dynamic forces acting on the ice may result in the development of linear fractures, called leads, as well as areas of ridged ice. In winter, with surface air temperatures usually well below freezing, water within an open lead will quickly freeze. Leads in the Arctic often form networks that extend over hundreds of kilometers, yet the overall Arctic ice concentrations remain high, generally above 95% (i.e., less than 5% open water), except near the ice margin. Refrozen leads in turn become covered with snow. Snow depths by the end of winter range widely depending on the region, the age of the ice, wind drift, and scour, but values of 30–60 cm can be considered typical.

Figure 1 Sea ice extent for the Northern Hemisphere for (a) March 2012 and (b) September 2012. Ice extent is defined as the region with an ice concentration of at least 15%. Arctic ice extent for September 2012 was the lowest over the period of satellite observations. The pink line shows the median ice extent for March and September, over a base period of 1979–2000. With spring, sunlight returns. Because of the overlying snow, the ice-covered part of the ocean may have an albedo (the reflection coefficient for visible-band radiation) as high as 0.85, contrasting sharply with open water, which, except at large solar zenith angles, has an albedo of less than 0.10. As spring advances, it becomes too warm for new ice to form in leads. Snow cover overlying the ice begins to melt, and, as a result, the surface albedo falls. During summer, melt ponds form (Figure 3). As more of the ice surface becomes covered with dark melt ponds, the regional surface albedo further decreases, fostering even more melt. As summer progresses, the open spaces between floes (leads), broadly linear in winter, become more amorphous. Ice floes move more freely and become more rounded, and melt ponds may drain. With the advent of autumn, remaining melt ponds freeze. New ice again starts to form in open-water areas, and the pack takes on its wintertime appearance of linear leads and jagged-edged snow-covered floes. Figure 4 gives examples of how autumn, early melt season, and late melt season ice appears in high-resolution satellite visible-band imagery. The description given here best characterizes the Northern Hemisphere sea ice cover. The Antarctic ice cover is more dynamic and behaves somewhat differently; in particular, the ice tends to be more fractured and summer melt ponds are less extensive.

Ice Formation and Thickness

Initial ice formation occurs at the surface in the form of small platelets and needles termed frazil ice. Frazil crystals are generally less than 3–4 mm. Continued cooling forms a slurry of unconsolidated frazil crystals, termed grease ice. Under calm conditions, frazil crystals freeze together, forming a solid, continuous ice cover of 1–10 cm thickness. However, in the more typical situation, a solid ice cover is inhibited by wind-induced turbulence in the water. Winds and waves advect

frazil ice downwind, where accumulations of up to 1 m thick can form in front of obstacles such as existing ice floes. Once the fraction of ice-covered area exceeds 30–40%, there is sufficient bonding between individual ice crystals to reduce their mobility, initiating the transition to a solid ice cover. Once the initial ice cover is formed, growth occurs mainly by bottom accretion.

Sea ice in the polar ocean has seasonally and regionally varying proportions of first-year (FY) ice, representing the ice growth of a single year, and multiyear (MY) ice, defined as ice that has survived at least one melt season. While, historically, some of the MY ice in the Arctic was over 10 years of age, much of the oldest MY ice is now gone. The majority of ice in the Antarctic is, by contrast, FY ice.

Because ice is a thermal insulator, the thicker it is the slower it grows, other conditions being equal. And because sea ice either ablates or stops growing during the summer, there is a maximum thickness of undeformed FY ice that can form during a specific year. The value depends upon the local climate and oceanographic conditions, reaching slightly over 2 m in the Arctic and as much as almost 3 m at certain protected Antarctic sites. Snow, an excellent insulator, will slow the growth rate of ice. During the winter, the heat flux from areas of open water into the polar atmosphere is significantly greater than the flux through even thin ice, and as much as 200 times greater than the flux through MY ice. This means that even if open-water and thin-ice areas comprise only a few percent of the winter ice pack, as is typical, these areas must still be considered in order to obtain realistic estimates of ocean–atmosphere thermal interactions.

If an FY ice floe survives a summer to become MY ice, the thickness of the ice added during the subsequent winter will be less than the change in thickness of nearby FY ice. This is because the ice growth at the bottom of the MY floe starts later in the season and occurs more slowly. Nevertheless, by the end of the winter, the second-year ice will be thicker than the nearby

Figure 3 Researchers on ponded sea ice. Reproduced from the National Oceanic and Atmospheric Administration/Department of Commerce online photo library (<http://www.photolib.noaa.gov/>).

Figure 4 Satellite visible band imagery of the Beaufort Sea. (a) In winter, leads freeze over rapidly; new ice appears smooth and relatively dark. The new ice lightens in appearance as it grows thicker, and it may be dusted by snow (image acquired 10 October 1997). (b) Snow melts soon after the surface air temperature rises above 0 °C. Ponds may cover nearly the entire surface of thinner, younger, less deformed ice, as shown in this image from 22 June 1998. (c) Later in the melt season, ponds generally do not cover as much of the surface. Image from 21 July 1998. All images cover 5 km by 5 km areas. Reproduced from Fetterer, Untersteiner, 2000. SHEBA Reconnaissance Imagery. National Snow and Ice Data Center, Boulder, Colorado, USA. http://nsidc.org/data/docs/noaa/g02180_sheba/index.html.

FY ice. Assuming that the above process is repeated in subsequent years, some ice will be ablated away each summer (largely from the top) and some added each winter (largely on the bottom). As the years pass, the ice melted on top each summer will remain the same (assuming no change in the climate over the ice), while the ice forming on the bottom will become less and less as a result of the increased insulating effect of the thickening overlying ice. Ultimately, a rough equilibrium will be reached, with the winter addition equaling the summer

ablation. At least in the past, steady-state MY ice floes in the Arctic could be layer cakes of 10 or more annual layers with total thicknesses in the range of 3.5–4.5 m. Much of the uncertainty in estimating the equilibrium thickness of such floes comes from uncertainties in the oceanic heat flux. In sheltered fiord sites in the Arctic where the oceanic heat flux is presumed to be near zero, MY fast ice (fast ice is ice that is locked to the shore) with thicknesses of up to roughly 15–20 m has been observed.

Conditions in the Antarctic are rather different. Surface melt rates within the ice pack are small compared with those in the Arctic. The stronger winds and lower humidity encountered over the ice pack also favor evaporation and minimize surface melting. The limited ablation that occurs appears to be controlled by heat transfer processes at the ice–water interface, so that the ice remains relatively cold throughout the summer. However, because most of the Antarctic sea ice is advected rapidly to the north, where it encounters warmer water at the Antarctic convergence and melts rapidly, only small amounts of MY ice remain at the end of summer.

Drift and Deformation

If sea ice was motionless, ice thicknesses would be controlled completely by the thermal characteristics of the lower atmosphere and the upper ocean. The ice cover would presumably have thicknesses and physical properties that would change slowly and continuously from region to region. However, even a casual examination of an area of pack ice reveals striking local lateral variations in ice thicknesses and characteristics. These changes are caused by ice movements produced by the forces exerted on the ice by winds and ocean currents. Such motions are rarely uniform and lead to the building of stresses. If these stresses become large enough, cracks (leads) may form and widen. Leads can vary in width from a few meters to several kilometers and in length from a few hundred meters to several hundred kilometers. As discussed in this article, during much of the year in the polar seas, once a lead forms, it is immediately covered with a thin skin of ice that thickens with time. This is an ever-changing process associated with the movement of weather systems as one lead system becomes inactive and is replaced by another oriented in a different direction.

While the process of lead formation will result in a variety of ice thicknesses, the pack ice thickness distribution observed in the Beaufort Sea in 1976 (Figure 5) reveals a significant amount of ice thicker than the 4.5–5.0 m maximum expected for steady-state MY ice floes. This thicker ice forms by the closing of leads, which commonly results in the piling of broken ice fragments into long, irregular pressure ridges, with a ‘sail’ extending above the water surface paired with a ‘keel’ extending below the surface. There are many small ridges, and large ones are rare. Nevertheless, the large ridges are very impressive: a sail height of 13 m and keel depth of 47 m have been reported in the Arctic (values not from the same ridge). Particularly heavily deformed ice commonly occurs in a roughly 150 km wide band running between the north coast of Greenland and the Canadian Arctic Islands and the south coast of the Beaufort Sea. The limited data available on Antarctic pressure ridges suggest they are generally smaller and less frequent than those in the Arctic Ocean. The general pattern of the ridging is also different in that the long, sinuous ridges seen in the Arctic Ocean are not common. Instead, the deformation can be better described as irregular hummocking accompanied by extensive rafting of one floe over another. Floe sizes are also smaller as the result of the passage of large-amplitude swells through the ice. These are generated by the intense Southern Ocean storms that move to

Figure 5 The distribution of sea ice drafts expressed as probability density as determined via the use of upward-looking sonar along a 1400 km track taken in April 1976 in the Beaufort Sea. All ice thicker than ~4 m is believed to be the result of deformation. The peak probabilities in the range between 2.4 and 3.8 m represent the thicknesses of undeformed multiyear ice, while the values less than 1.2 m come from ice that formed more recently in leads.

the north of the ice edge and result in the fracturing of the larger floes, with the large vertical motions facilitating the rafting process.

Pressure ridges are of considerable importance. First, they change the surface roughness at the air–ice and water–ice interfaces, thereby altering the effective surface tractions exerted by winds and currents. Second, they act as plows, forming gouges in the sea floor up to 8 m deep when they ground and are pushed along by the ungrounded pack as it drifts over the shallower (<60 m) regions of the polar continental shelves. Third, as the thickest sea ice masses, they are a major hazard that must be considered in the design of offshore structures. Finally, and most important, the ridging process provides a mechanical procedure for transferring the thinner ice in the leads directly and rapidly into the thickest ice categories. Figure 6 provides a schematic of basic sea ice types, deformation processes, and morphology. Figure 7 illustrates various sea ice formations, including pressure ridges, from photographs taken at the surface and from aircraft.

The large-scale pattern of ice drift in the Arctic has two main features: the Beaufort Gyre, a large clockwise circulation centered in the Beaufort Sea, and the Transpolar Drift Stream, a motion of ice from the Siberian shelves and across the central Arctic Ocean to the Fram Strait. Nearly all of the sea ice that exits the Arctic Ocean does so through the Fram Strait. This large-scale pattern of ice drift broadly reflects the distribution of sea level pressure and hence the surface wind field over the Arctic Ocean (see Figure 2 in Arctic Climate). The time required for the ice to complete one circuit of the Beaufort Gyre averages 5 years, while the transit time for the Transpolar Drift Stream is roughly 3 years. There are many interesting features of the ice drift that occur over shorter time intervals. For instance, in response to the often high frequency of cyclonic storm systems

over the central Arctic Ocean in summer and early autumn, the Beaufort Gyre may run backward (counterclockwise) over appreciable periods of time. Typical pack ice velocities range from 0 to 20 cm s⁻¹, although extreme velocities of up to 220 cm s⁻¹ (4.3 knots) have been recorded during storms. During winter, periods of zero ice motion are not rare. During summer, when considerable open water is present in the pack, the ice appears to be in continuous motion. The highest drift velocities are observed near the edge of the pack. Not only are such locations commonly windy, but also the floes are able to move toward the free edge with minimal interfloe interference. Ice drift near the Antarctic continent is generally westerly, becoming easterly further north, but in all cases showing a consistent northerly diverging drift toward the free ice edge.

Geophysical Significance

In winter, sea ice suppresses vertical exchanges of heat (turbulent latent and sensible heat fluxes) between the upper ocean, with its temperature close to the salinity-adjusted freezing point, and a much colder atmosphere (sometimes lower than -40 °C). At the same time, sea ice limits the upward longwave radiation flux from the surface. Snow cover that may be present atop the sea ice cover adds to the insulating effect. In spring and summer, air-sea temperature differences are much smaller than in winter so the insulating effect is not as important. However, because of the high surface albedo of the sea ice cover, much of the solar energy is reflected back to space; even bare ice has a much higher albedo than open water. Where the ocean is largely covered by melting sea ice in summer, the surface has a constant skin temperature. This serves to limit the magnitude of turbulent heat fluxes and the upward longwave radiation flux. All of these effects can be viewed as helping to reinforce the basic temperature gradient between the polar regions and lower latitudes that drives poleward atmospheric energy transports. On a more regional basis, the boundary between sea ice and open water at the surface during winter is characterized by sharp horizontal temperature gradients extending through a considerable depth of the atmosphere. Consequently, shifts in the location of the winter ice margin can alter the formation and tracks of extratropical cyclones and their associated precipitation. Polynyas (semipermanent areas of open water and thin ice at sites where climatically much thicker ice would be anticipated) are another source of moisture to the polar atmosphere, and they can affect precipitation and cloud cover.

Changes in the brine volume of sea ice have geophysical significance as well. When seawater freezes, roughly one-third of the salt in the seawater is initially trapped within the ice in the form of brine inclusions. As a result, initial ice salinities are typically in the range of 10–12 ppt. At low temperatures (<-8.7 °C), solid hydrated salts also form within the ice. The composition of the brine in sea ice is a function of the temperature, with the brine composition becoming more saline as the temperature decreases. Therefore, the brine volume (the volumetric amount of liquid brine in the ice) is determined by the ice temperature and the bulk ice salinity. Not only does temperature vary vertically in the ice floe but also salinity decreases as the ice ages, reaching a bulk value of about

3 ppt in MY ice. Brine volumes are usually lower in the colder upper portions of the ice and higher in the warmer lower portions. They are particularly low in the part of MY ice above sea level, from which the salt has drained almost completely. The upper layers of thick MY ice produce excellent drinking water when melted. Hence, while brine volume is the single most important parameter controlling the thermal, electrical, and mechanical properties of sea ice, these properties exhibit large changes both vertically in the same ice floe and between floes of differing ages and histories. To add complexity to this situation, exactly how the brine is distributed within the floe also affects ice properties such as ice strength and its electro-magnetic characteristics.

The Arctic Ocean is characterized by a low-salinity surface layer up to about 50 m thick that forms as the result of the influx of fresh water from river discharge (particularly from the great rivers of Siberia, the Ob, Yenisei, and Lena; and, on the North American side, the Mackenzie), positive net precipitation over the Arctic Ocean itself (an excess of precipitation over evaporation), and the import of fairly low-salinity waters through the Bering Strait. This stable, low-density surface layer prevents the heat contained in the comparatively warm (temperatures of up to +3 °C) but denser and more saline water beneath the surface layer from affecting the ice cover. As sea ice rejects roughly two-thirds of the salt initially present in the seawater from which the ice forms, the freezing process is equivalent to distillation, producing both a low-salinity component (the ice layer itself) and a high-salinity component (the rejected brine). Both components play important geophysical roles. Over shallow-shelf seas, the rejected brine, which is dense, cold, and rich in CO₂, sinks to the bottom, ultimately feeding the deep-water and bottom-water layers of the world's oceans. Such processes are particularly effective in regions where there are large polynyas. Because this 'salt pump' removes CO₂ from the atmosphere, it has been hypothesized that it is a process contributing to the decrease in CO₂-air ratios observed in ice core samples deposited during times of maximum glacial advance (colder = more sea ice formation = more CO₂ removed from the atmosphere).

Sea ice also has important biological effects. It provides a substrate for a special category of marine life, the ice biota, consisting primarily of diatoms. These form a significant portion of the total primary production and, in turn, support specialized grazers and species at higher trophic levels, including amphipods, copepods, worms, fish, and birds. At the upper end of the food chain, seals and walruses use ice extensively as a platform on which to haul out and give birth to young. Polar bears use the Arctic ice as a platform while hunting. Also important is that in shelf seas such as the Bering and Chukchi, which are well mixed in the winter, the melting of the ice cover in the spring lowers the surface salinity, increasing the stability of the water column. The reduced mixing concentrates phytoplankton in the near-surface photic zone, thereby enhancing the overall intensity of the spring bloom.

Variability, Trends, and the Future

While the most notable aspect of variability in sea ice extent is its large seasonal cycle, extent for all months can vary markedly

from year to year on both a regional basis and for the two hemispheres as a whole. A key driver of variability in ice extent is atmospheric circulation patterns. While changing circulation patterns affect the drift of ice (the dynamic effect), they also affect conditions of temperature, cloud cover, and snowfall that influence ice growth and melt (thermodynamic effects).

As a good example of forcing by atmospheric circulation, it has been shown that September Arctic ice extent following summers with a high frequency of extratropical cyclone activity over the central Arctic Ocean tends to be greater than that following summers with a low frequency of cyclone activity (which tend to feature a persistent Beaufort Sea high). When the prevailing circulation is more cyclonic, the sea ice motion tends to be divergent, spreading the ice over a larger area and increasing ice extent. The stormy cyclonic pattern also tends to bring fairly cool conditions and even snowfall events, inhibiting summer melt. In contrast, an anticyclonic circulation pattern favors ice convergence and relatively warm conditions. These tend to reduce ice extent. Recently, considerable attention has been paid to the importance of what some have called the summer Arctic Dipole Anomaly pattern. In its positive mode, the pattern features above-average sea level pressure centered north of the Beaufort Sea (essentially, a strong Beaufort Sea high) and below-average pressure centered over the Kara Sea. Resulting southerly winds between the pressure anomaly centers at the surface favor transport of ice away from the coasts of Siberia and Alaska toward the North Pole, as well as strong melt in the East Siberian and Chukchi seas. The pattern also favors a strong sea level pressure gradient across the Fram Strait (between Greenland and Svalbard), enhancing wind-driven transport of sea ice out of the Arctic Ocean and into the North Atlantic. The negative phase has a broadly opposing pressure anomaly pattern. The positive pattern was very well developed throughout the summer of 2007 and was a key factor in that year having the second lowest September sea ice in the satellite record (based on data through 2012).

As another example, links have been established between Arctic sea ice conditions and the phase of the Arctic Oscillation (AO) during winter (the AO is also known as the Northern Annular Mode). From the late 1980s through the mid-1990s, the winter AO frequently exhibited its positive phase. This was manifested by reduced winter sea level pressure both over the Arctic Ocean and in the vicinity of the Icelandic Low. The attendant shift in the wind field and hence the ice drift led to the production of more thin FY ice along the Siberian and Alaskan coasts. It also flushed some of the Arctic's store of old, thick MY ice through the Fram Strait and into the North Atlantic. With extensive thin ice in spring, the stage was set for large areas of the pack ice to melt out in summer. This process helps to account for the extreme September sea ice minima that started to be seen in the late 1990s and early 2000s.

Although atmospheric circulation patterns are the main driver of year-to-year variability in ice extent, ocean circulation variability also plays a role. Development of the Weddell Sea polynya in Antarctica is a good example of ocean forcing. This hole in the sea ice cover can occupy an area of over 200 000 km², comparable in size to Great Britain. The polynya appears on an irregular basis (the largest was observed in

1974–76), and it is highly variable in location and shape. While a number of explanations have been offered to explain the development of the feature, it appears that an important role is played by a nearby massive seamount called the Maud Rise. There is evidence from modeling studies that modest variations in the large-scale oceanic flow past the Maud Rise seamount result in the shedding of a horizontal cyclonic eddy from its northeast flank, transmitting a divergent Ekman stress into the sea ice and leading to a crescent-shaped opening in the pack. The opening is then further enhanced by intense heat losses to the atmosphere from the open water, inducing oceanic convection.

Interannual variability in total Northern Hemisphere ice extent is superimposed upon downward linear trends in extent in all months; they are smallest for the winter months and largest for September (*see* Figure 10 in Arctic Climate). Especially interesting is that the general climatic warming widely viewed as driving the basic downward trend in Northern Hemisphere sea ice extent has changed the response of the ice cover to natural climate variability in ways that appear to have enhanced the trend. Because of the general thinning of the ice cover over the past few decades, large areas are more vulnerable to melting out in summer, making unusual circulation patterns such as the strongly developed Arctic Dipole Anomaly seen in 2007 now more effective in forcing large summer ice losses. Furthermore, the thermodynamic thinning process was dynamically enhanced by the shift in the AO from the late 1980s through the mid-1990s. The ongoing decline in Arctic sea ice extent appears to be a dominant driver of what is known as Arctic amplification – the observed enhanced warming at the Arctic surface and lower troposphere relative to the globe as a whole. With more open water in spring and summer, more solar energy is absorbed by the ocean mixed layer compared to past decades; this heat is then released upward in autumn and winter, heating the atmosphere.

By contrast, the Southern Hemisphere sea ice cover has in general expanded slightly since the late 1970s. Based on satellite data through 2010, the overall upward trend for the Southern Hemisphere is dominated by increases in some sectors that are partly countered by negative trends in others. When examined through the annual cycle, there are positive linear trends in Antarctic sea ice cover as a whole for all months, smallest in February and largest in May.

Why has Southern Hemisphere sea ice extent not experienced an overall downward trend like that seen in the Northern Hemisphere? While a number of explanations have been proposed, all of which may contribute, changes in atmospheric circulation appear to play a dominant role. A study of satellite-tracked sea ice motion for the period of 1992–2010 reveals large and statistically significant trends in Antarctic ice drift, which, in most areas, can be linked to local winds. This analysis provides strong evidence that wind-driven changes in ice advection (causing ice to drift more to the north) are a dominant driver of ice concentration trends around much of West Antarctica, whereas wind-driven thermodynamic changes (effects on temperature) dominate elsewhere (Figure 8).

What changes can we expect in our planet's sea ice cover through the twenty-first century? Most hindcast simulations from coupled global climate models that incorporate observed

Figure 8 Linkages between wind-driven changes in ice motion and ice concentration changes in Antarctica over the period 1992–2010. (a) Ice motion trend vectors overlaid on ice concentration trends. (b) 10 m wind trend vectors overlaid on trend in sea-level pressure. White, gray, and black contours show underlay field trends significant at 90, 95, and 99%, respectively; black vectors have meridional trends significant at $>90\%$; and magenta contour in (b) shows the extent of concentration trends. climate forcings show declining Northern Hemisphere ice extent for September over the period of observations. While this provides strong evidence for a role of greenhouse gas forcing on the observed downward trend, trends simulated by most models are smaller than observed. This is true even for the newer generation of models contributing to the

Intergovernmental Panel on Climate Change Fifth Assessment Report, which is to be published in 2014. The emerging view is that the Arctic will lose essentially all of its summer sea ice cover by the end of the twenty-first century, perhaps as early as 2030–40. The Arctic amplification of air temperature changes noted in this article will become more pronounced. Many

modeling studies show that this outsize warming may result in changes in patterns of atmospheric circulation and precipitation extending well beyond the Arctic. Another common feature of climate model simulations is a much slower decline in sea ice extent in the Southern Hemisphere.

Introduction

Snow blankets more than half of the Northern Hemisphere each winter, remaining in place for periods ranging from less than a month (typically south of 40° N) to more than 8 months of the year (typically north of 60° N). In the Southern Hemisphere, the coverage is less extensive, but still substantial. If the perennial snow covers of the Greenland and Antarctic ice sheets are included, along with the seasonal snow cover that forms on lake and sea ice, then the total percentage of the Earth's surface covered by snow during some period of each year is considerable. This blanket of snow is a complex, layered material that can exhibit a high degree of spatial heterogeneity. Year-to-year variations in coverage and properties can be large and they have a direct and immediate impact on the Earth's climate. In this article, the major types of snow cover are introduced and the layered nature of the snow is discussed. The role of the snow in moderating the exchange of energy and mass with the atmosphere is also described.

Snow Cover and Its Importance

The term 'snow cover' is directly analogous to the term 'formation' when discussing layered sedimentary or metamorphic rocks. Both the sequence and character of the layers, and the lateral variation of each layer (facies changes), contribute to the overall properties of the formation. Similarly, the bulk physical and thermal properties of a snow cover, the properties that are of importance in moderating the exchange of energy and mass between the Earth and the atmosphere, are an aggregate of the properties of the individual layers. For each layer, these properties are the result of the conditions (snowfall, wind, temperature) that prevailed when the layer was deposited, and the post-depositional conditions (temperature, temperature gradients, snow overburden, liquid water percolation, solar radiation) to which the layer was subjected after deposition. Because both deposition and post-deposition conditions vary across the landscape, the layers themselves vary. In order to understand the role of snow cover in atmospheric processes, the layered nature and spatial variability of the material need to be considered.

Much of the impact of snow on climate and atmospheric processes arises because of its high albedo and low thermal conductivity. Snow cover reflects up to 85% of incoming short-wave solar radiation, significantly reducing winter temperatures and retarding melting in the spring. At the same time, snow is an excellent insulator, so it can effectively lower the rate of heat loss from the ground or an underlying ice surface, thereby maintaining higher winter soil temperatures or retarding the rate of sea and lake ice growth. The total winter energy exchange across a snow cover is a complex balance between these two competing processes. Snow cover is also important because it traps aerosols and other atmospheric particulates

like a filter, storing these until the snow melts, then releasing them abruptly. Snow can control, through thermal and physical means, the release of trace gases like CO₂ from subnival plants and soils during the winter, and it functions as a temporary storage reservoir of water, stockpiling winter precipitation then allowing it to run off in a much shorter period of time than it otherwise would have had it not fallen as snow. In some cases in higher latitudes where the snow lasts many months, as much as 80% of the annual river discharge can be from snow melt, and this discharge may occur in a period of less than 2 weeks.

Perennial and Seasonal Snow Covers

Because of their fundamentally different layered structures, it is customary to distinguish between perennial and seasonal snow covers. Seasonal snow covers are deposited in the fall and melt away completely each spring; therefore, they never become very deep. Perennial snow covers form at higher levels on glaciers and ice sheets, where the combined decrease in temperature and increase in snowfall precipitation with altitude is sufficient to allow winter snow accumulation to survive the summer melt. Snowfall of the following winter is deposited on the residual snow of the previous year, forming a sequence of annual layers of snow that can be tens to hundreds of meters thick before compaction at depth converts the snow into glacier ice.

Separate but related climate classification systems for perennial and seasonal snow covers have been suggested and are useful when thinking about both local and global variations in snow cover. For the perennial snow on glaciers and ice sheets, increasing elevation results in a decrease in melting. As a consequence, snow characteristics vary with elevation (**Figure 1**). At the lowest elevation, the melt removes all of the winter snow, and a seasonal rather than perennial snow pack forms each year. Higher, the snow pack survives the summer melt, but percolation of melt water into the snow pack and subsequent refreezing produce extensive icy features like the ice lenses and percolation columns. At the highest elevations, no melting takes place and the dry snow facies is observed. On a steep alpine glacier, the entire sequence is compressed into a distance of tens of kilometers. On ice sheets, sequence may spread over distances of hundreds of kilometers.

For seasonal snow covers, local climate rather than elevation determines the prevailing snow cover characteristics, and this local climate can be represented by three simple binary variables: winter temperature, winter precipitation, and wind. High and low values for each of these variables (**Figure 2**) define eight possible types of seasonal snow covers, most of which have a counterpart in the glacier facies system shown in **Figure 1**. For example, under warmer, wetter winter conditions, a maritime snow cover will develop. This snow cover tends to be deep (>1 m) and warm (near or at freezing temperatures), and

Figure 1 The glacier facies classification of Benson (1962), describing variations in the characteristics of the perennial snow cover found on glaciers and ice sheets. With increasing elevation, there is a decrease in the amount of melting and, as a consequence, a decrease in the amount of icy features in the winter snow pack. At the lowest level, all of the winter snow melts in the summer and the snow cover is essentially seasonal; at the highest level, no melting takes place and the snow has no features in it related to melting. From Benson CS (1962) Stratigraphic studies in the snow and firn of the Greenland Ice Sheet. SIPRE Research Report 70, CRREL.

Figure 2 A dichotomous classification of seasonal snow covers based on winter temperature, precipitation, and wind. In [Figure 3](#), a typical snow stratigraphy for each class is shown. Broad similarities in snow characteristics exist between the seasonal snow classes and the glacier facies shown in [Figure 1](#). From Sturm M, Holmgren J, Liston G (1995) A seasonal snow cover classification system for local to global applications. *Journal of Climate* 8: 1261–1283.

exhibits similar icy features to those observed in the percolation facies on glaciers (compare [Figure 3](#) to [Figure 1](#)). Similarly, alpine, tundra, and taiga snow cover classes exhibit features found in the dry snow facies on glaciers. The stratigraphic diagram and key in [Figure 3](#) suggest the main snow cover characteristics associated with each climate class for seasonal snow.

Layer by Layer Development of a Snow Cover

Snow cover builds up layer by layer. The initial characteristics of each layer are determined by how much solid precipitation falls, whether the precipitation is accompanied by wind, and the prevailing temperature at the time of deposition. After deposition, each layer is subjected to mechanical and thermal metamorphic processes that alter the layer characteristics. These vary in intensity and duration depending on when the layer was deposited, its height in the snow pack and the number of overlying layers, the prevailing conditions at the snow surface, and the temperature and temperature gradients in the snow pack as a whole. At any given time, the characteristics of each layer in the snow are a product of its initial deposition and post-depositional metamorphism.

Layer Deposition and Densification

Almost 80 different types of falling snow crystals have been identified. The particular crystals that accumulate at the Earth's surface in a snow storm are determined by the temperature and humidity in the layers of air through which the crystals

Figure 3 Typical snow stratigraphy for the six seasonal classes listed in Figure 2. From Sturm M, Holmgren J, Liston G (1995) A seasonal snow cover classification system for local to global applications. *Journal of Climate* 8: 1261–1283.

fall and grow. However, crystal form is far less important than the rate of snowfall, the wind speed, and the temperature in determining the initial characteristics of a snow layer. In general, low temperatures, low wind, and low rates of snow fall produce the lowest-density layers of new snow (Table 1).

Once deposited, new snow layers densify rapidly. Initially, much of this densification is a result of thermodynamic

instability. The sharp points and intricate branches of newly fallen snow crystals have high radii of curvature; the water vapor pressure over these highly curved surfaces is greater than elsewhere, so there is a net loss of water molecules from pointed areas to the air spaces in the snow, or to other areas on crystals that have lower degrees of curvature. The crystals rapidly break down and the resulting fragments become more rounded (Figure 4). The breakdown reduces the size of the crystals, increases the number of individual snow grains, and decreases the degree to which the crystals interlock. As a result, the entire snow layer settles.

As additional new layers of snow are added to the snow pack, the overburden load (σ) on buried layers increases. For these layers, compaction due to vertical stresses begins to dominate the snow densification process. The response of the snow to these stresses has been modeled by assuming the snow layer behaves like a viscous fluid (eqn [1]).

Table 1 The density of newly deposited snow

Deposition conditions	Density (g cm^{-3})
No wind, low rate of snowfall, cold	0.02–0.05
Low wind, low rate of snowfall	0.05–0.10
Moderate wind, high rate of snowfall	0.20–0.35
Moderate wind, low rate of snowfall	0.35–0.40
High wind	0.40–0.55

Figure 4 Changes in a snowflake held at a constant temperature of -11.5°C for a total period of 57 days (indicated by small numbers). The snowflake grew in the atmosphere under conditions of supersaturation with respect to water vapor. Once deposited, the sharp points and thin branches were thermodynamically unstable and the snowflake metamorphosed, even in the absence of a temperature gradient or overburden stress. From Bader H, Haefeli R, Bucher E, Neher J, Eckel O, Thams C (1939) *Der Schnee und seine Metamorphose* (Snow and its Metamorphism), US Army SIPRE Translation 14, 1954.

$$-\frac{1}{h} \frac{dh}{dt} = \frac{1}{\rho} \frac{d\rho}{dt} = \frac{\sigma}{\eta_c} \quad [1]$$

In eqn [1], h is the thickness of the layer (m), t is time (s), ρ is the layer density (kg m^{-3}), and η_c is the compactive viscosity. Values of η_c (Pa s) have been determined from observations of the settlement of natural snow layers, from uniaxial strain compressive tests, and from depth–density profiles on glaciers and ice sheets. The combined results show wide scatter, but individual sets of data are usually fitted to the relation in eqn [2], where k is a factor that depends on the type of snow cover (Figure 1 through 3).

$$\eta_c = \eta_0 e^{kp} \quad [2]$$

The effective viscosity term incorporates a number of physical mechanisms including gravity-driven movement of snow grain

centers of mass toward each other, vapor and volume diffusion, and sintering. Not surprisingly, viscosity factor values vary widely depending on the temperature, liquid water content, and grain characteristics of the snow – i.e., the snow cover class (Table 2). Colder, drier, finer-grained layers of snow tend to be more viscous than warmer, wetter, layers with larger grains, and therefore compact more slowly.

In the absence of melting or the introduction of liquid water, snow layers will continue to densify until they reach a limiting density of about 0.6 g cm^{-3} . By this time, the snow grains will have metamorphosed until they have become highly rounded, a shape that minimizes their surface free energy. The rounded grains will be in close contact with each other, and the grain arrangement will approximate that of hexagonal close-packing of ice spheres. Further densification

Table 2 Compactive viscosity factors for three classes of snow cover

Snow cover type	k-value ($\text{m}^3 \text{kg}^{-1}$)
Maritime	18–22
Alpine/taiga	35–60
Tundra	>70

will require actual deformation of the individual grains of snow, or the influx and refreezing of melt water in pore spaces. The overburden stresses required to achieve this further deformation are only realized in the deep perennial snow packs found on glaciers and ice sheets.

Snow layers deposited during windy conditions (wind slabs) have much higher initial densities than other new snow layers. The wind tumbles snow crystals as it transports them, breaking the more fragile crystal junctions and pulverizing the crystals in general. The resulting grains are actually crystal fragments, often less than 0.1 mm in length, and these shard-like grains (Figure 5), when they come to rest, pack well and sinter together into a cohesive slablike layer. Initial densities for wind-transported layers of new snow range from 0.35 to 0.6. The upper limit occurs for the same physical reasons as discussed before. Due to their high initial densities and cohesiveness, wind slabs are highly resistant to compaction and often remaining at a fixed density after deposition.

There has been much discussion and experimentation to determine the wind speed necessary to transport snow. The transport takes place through three mechanisms: creep, saltation, and suspension. Creep consists of the rolling movement of grains along the snow surface under the action of the wind. Saltation is the movement of grains along the surface by jumping and ricocheting after impact by other grains. Suspension is the movement of grains in the wind stream at some level above the snow surface. The threshold shear velocity, u^* , at which transport occurs is usually estimated by assuming a logarithmic-shaped wind profile and projecting the 10-m high wind speed (u_{10}) down to the snow surface (u^*). In general the value of u_{10} is between 18 and 30 times the value of u^* . Experimental studies indicate that when u_{10} is greater

**Figure 5** Wind-pulverized snow grains from Arctic Alaska, showing irregular shapes and thick bonds due to rapid sintering after deposition.

than 6 m s^{-1} transport will occur if the snow has fallen recently. If the snow is new and falling while there is wind, transport will occur with wind of 5 or even 4 m s^{-1} . If the snow is aged, was previously transported by the wind, or has undergone some melt-freeze processes, speeds in excess of 30 m s^{-1} may be needed before the snow will start to be transported (Figure 6).

In similar fashion, the flux of snow transported by the wind is a strong function of the wind speed, with increasing speeds producing a marked increase in the total amount transported (Figure 7). For values of u^* between 0.2 and 0.44 m s^{-1} , saltation dominates the transport, but for u^* values in excess of 0.44 m s^{-1} , suspension exceeds saltation in transporting snow.

One other consequence of wind transport of snow is the development of a wide range of drift deposit and erosion

**Figure 6** The critical wind shear velocity (u^*) as a function of snow hardness, which is a good measure of the type of snow. Increasing hardness, common for wind slabs and layers of snow that have undergone melt-freeze, requires considerably higher winds to mobilize these types of snow. u_{10} is the wind speed measured at a standard height of 10 m. From Kind RJ (1981) Snow drifting. In: Gray DM, Male DH (eds). Handbook of Snow, pp. 338–359. Toronto: Pergamon.**Figure 7** Snow transport rates for saltation (solid curve) and suspension (broken curve) as a function of wind shear velocity (u^*). The wind speed at 10 m height is approximately 18–26 times u^* . At $u^* = 0.44$ (10 m height wind speeds of $8\text{--}11 \text{ m s}^{-1}$), suspension begins to transport the majority of the wind-borne flux of snow. From Liston GE, Sturm M (1998) A snow-transport model for complex terrain. Journal of Glaciology 44: 498–516.

features at the snow surface. These features include ripple marks, dunes, barchans, and sastrugi. Surprisingly, little is known about the relationship between these features and the wind speed, the temperature, and the snow conditions necessary for their formation.

The final, and most efficient, method for densifying a layer of snow is through the infiltration of melt or rain water into the snow cover, followed by subsequent refreezing. Water can infiltrate, surround grains as thin films or lie in veins along grain junctions, and refreeze to produce large multiparticle grains. Water can also percolate downward in pipelike structures called percolation columns, or spread out along stratigraphic boundaries (owing to variations in the hydraulic conductivity of the snow). When this water refreezes, ice lenses and layers are created. Frequently, a single infiltration event will produce ice layers at multiple levels in the snow pack. Densities in excess of 0.6 g cm^{-3} , sometimes even as high as 0.9 g cm^{-3} , can result. This mechanism is commonly observed in ephemeral and maritime seasonal snow covers (Figures 2 and 3), and in the percolation facies for perennial snow (Figure 1).

Snow Metamorphism

In addition to compaction and densification, several other metamorphic processes can affect layers of snow. These processes result chiefly in changes in snow grain characteristics and bonding, which in turn affect the thermal conductivity, air permeability, and albedo of the snow. The processes are typically divided into 'wet' and 'dry' categories because different snow grain characteristics are produced depending on whether liquid water is present. Further metamorphic subdivisions are shown in Table 3.

For wet snow metamorphism, the degree to which grains and a snow layer are changed is mainly a function of how much water is present. For low liquid contents ($<5\%$ by weight), the water in the snow exists as thin films and isolated pockets or veins around grains; continuous ice grain and air space pathways still exist through the snow layer. This is called the pendular regime. Under this regime, snow grains will rapidly round, and clusters of grains, looking much like bunches of grapes, will form as a result of the minimization of surface free energy. The clusters themselves are quite strong because the bonds between the spherical grains are still intact and substantial. The wet snow pack will have considerable bearing strength. Spring skiing, which can be excellent, takes advantage of these ball-bearing like grain clusters and the general strength and cohesiveness of this type of wet snow metamorphism. If the temperature of the snow drops and the grain clusters freeze, they will take on the slightly more amorphous shapes of melt-grain clusters (Figure 8), while at the same time the strength of the layer will increase dramatically as all the interstitial water freezes. For higher liquid water contents, snow grains and air spaces become surrounded and isolated by the liquid water

Figure 8 Melt-grain clusters showing the well-rounded grains and the high degree of contact between grains.

present in the layer. This water begins to drain downward under the influence of gravity and is called the funicular regime. Once again, when surrounded by water, the snow grains will round, but now boundaries between grains will not be thermodynamically stable and will melt rapidly, creating a slush. The slush has little or no bearing strength, and can even flow like a fluid under certain conditions. The grains themselves, if surrounded by water at 0°C for long enough (24–36 hours), will metamorphose into oblate spheroids (Figure 9).

In the absence of liquid water, snow will metamorphose in one of two ways depending on the temperature gradient imposed on the snow. Water vapor density over ice is a strong positive function of temperature, so temperature gradients in the snow give rise to water vapor density gradients in the air spaces in the snow and a diffusive flow of vapor from warmer to colder grain surfaces. For convenience the temperature gradient is often defined as the difference between the basal and surface temperatures of the snow cover, divided by the thickness of the snow (Figure 10), but in reality the actual temperature gradient varies continuously with both time and height in the snow. For example, rapid fluctuations in air temperature can produce very large temperature gradients near the snow surface, at least for short periods of time. Experimental work has shown that when the temperature gradient exceeds a magnitude of approximately $0.25^{\circ}\text{C cm}^{-1}$, kinetic crystal growth will occur. If the gradient is lower, equilibrium growth takes place. Not surprisingly, temperature gradients in thick perennial snow covers tend to be lower than those in the thinner seasonal snow covers, particularly thin taiga, tundra, and alpine seasonal classes that can be subjected to very low air temperatures in the winter. As a result, kinetic growth is common in seasonal snow covers but occurs infrequently (often only in autumn) in perennial snow covers.

Figure 9 Snow slush, showing the oblate spheroid shape of the grains and the complete lack of bonding. From Colbeck SC (1986) Statistics of coarsening in water-saturated snow. *Acta Metallurgica* 34, 347–352.

Figure 10 (a) Temperature profiles and (b) computed vertical temperature gradients from the snow cover on the ice of the Beaufort Sea north of Alaska. The temperature profiles are not linear, and as a consequence, the temperature gradients vary in a complex way with height in the snow. Note that at some heights and times the gradient is below the critical magnitude of $0.25^{\circ}\text{C cm}^{-1}$ and kinetic growth will not occur.

Equilibrium crystal growth, also widely known as ‘equi-temperature metamorphism’ (ET-metamorphism) occurs when temperature gradients in the snow pack are less than $0.25^{\circ}\text{C cm}^{-1}$. These low temperature gradients produce weak

Figure 11 The initial stages of kinetic growth metamorphism. The grains are starting to exhibit distinct faceting.

Figure 12 At-depth hoar cup, shown in typical growth position. The hexagonal pyramidal cup opens downward because the flow of water vapor is upward. Heavy striae can be seen on all crystal facets. This is the late stage of kinetic growth metamorphism.

water vapor density gradients in the snow and low rates of vapor diffusion. The rates are so low that the supply of vapor to a growing crystal, rather than crystal growth dynamics, controls the growth. Rounded, well-bonded grains result.

Kinetic growth, also widely known as ‘temperature-gradient metamorphism’ (TG-metamorphism), produces ornate, faceted

crystals commonly referred to as 'depth hoar.' In this case, temperature gradients imposed on the snow are of a large enough magnitude to produce a flux of water vapor that exceeds the rate at which the crystal can grow. Crystal growth dynamics, rather than vapor supply, control both the growth rate and the crystal form, producing crystals with distinct sharp-edged facets, well-defined interfacial angles, and surface striae (Figure 11 and Figure 12). Unlike the case for equilibrium growth, intergrain bonds are weakened and reduced in number during kinetic growth, producing layers that tend to be brittle and weak. This has two important ramifications: the brittle layers can shear easily and often create failure planes that are responsible for the release of avalanches. Second, the poor bonding creates layers that have low thermal conductivity. In absence of air movement in the snow, these layers provide excellent insulation that contributes to the retention of heat in the ground or ice underlying the snow cover.

Energy and Mass Exchange across a Snow Cover

It is beyond the scope of this article to address in full the mass and energy exchange over a snow cover, but a few points particular to snow are discussed. The reader should also see articles on surface energy balance, albedo, turbulence,

boundary layer meteorology, surface roughness, and solar radiation for more details.

Heat transfer across a snow cover occurs mainly by conduction through the ice network of grains, by conduction across the air-filled pore spaces in the snow, and by diffusion of vapor across the pore spaces. The thermal conductivity of ice is more than 100 times higher than that of air, so the conduction of heat across air spaces is thought to contribute relatively little to the total. The heat transported by vapor diffusion, in contrast, is thought to contribute as much as 40%, particularly at temperatures near freezing when the vapor flux is high. This diffusive vapor transport is envisioned as occurring in a 'hand-to-hand' manner across pore spaces, with vapor diffusion from the warm side of snow grains balanced by vapor condensation on the colder side.

Because the contributions of these three individual mechanisms are difficult if not impossible to separate, in practice they are always lumped together by reporting an 'effective' thermal conductivity for the snow. Both solid body conduction through the ice network and vapor diffusion are driven by the temperature gradients in the snow, suggesting that a simple heat flow equation can be used to model the flux of heat across the snow (eqn [3]).

$$q = k_{\text{eff}} \frac{dT}{dz} \quad [3]$$

Figure 13 A compilation of most published values of the thermal conductivity of snow. There is nearly an order of magnitude scatter at any given density, and this scatter is real. It arises from differences in snow cover characteristics. From Sturm M, Holmgren J, König M, Morris K (1997) The thermal conductivity of seasonal snow. *Journal of Glaciology* 43: 26–41.

Here q is the vertical heat flow through the snow cover, dT/dz is the temperature gradient across the snow, and k_{eff} is the effective thermal conductivity of the snow. However, the driving temperature gradient in the ice network may be quite different from the gradient across pore spaces that drives vapor diffusion, in which case eqn [3] may be an oversimplification. Be that as it may, it is customary to describe the heat transfer using eqn [3] and assigning an appropriate value for k_{eff} .

Figure 13 shows compilation of most measured values of k_{eff} as a function of density. As the density of the snow increases, so in general does the value of k_{eff} . In many climate models, regression equations relating k_{eff} to density (often using the viscous snow compaction (eqns [1] and [2]) to determine the snow density) are used to set the thermal conductivity of the snow. However, as the figure shows, the scatter in k_{eff} at any given density is large and real. It is the result of differences in the bonding of the snow, and perhaps also due to variations in snow temperature. For a given density, higher temperatures and better bonding between grains lead to higher values of thermal conductivity. Given the scatter, care should be exercised when choosing a value of k_{eff} for modeling. The values should be consistent with the type of snow cover (Figure 1 through 3) as well as a k_{eff} -density relationship. For improved accuracy, a value of k_{eff} for each layer of snow should be determined; then the bulk value for the entire snow cover should be computed using a series-type solution.

Convective heat transfer is also known to operate in snow and complicates the energy exchange across a snow cover. Two types of convection have been reported: buoyancy-driven convection, and convection forced by the wind (wind-pumping). The former has been documented only in a highly permeable snow covers like taiga snow. This snow cover often wholly comprises layers of large, poorly bonded kinetic growth crystals called depth hoar. The layers have extremely high values of air permeability and, owing to low winter air temperatures, are subjected to temperature gradients of high magnitude, both conditions favorable for buoyancy-driven convection. Convective air flow velocities of several millimeters per second have been computed based on observations of temperature fields in the snow, and these air flow speeds are sufficient to increase the heat transfer rate by a factor of 3. The prevalence of buoyancy convection in other types of snow covers may be low, but this has not been shown experimentally.

Forced convection also probably occurs in some snow covers. Theory indicates that pressure differences arising when wind blows across surface irregularities like dunes and sastrugi are most likely to produce a flow of air that can move both heat and mass (in contrast to turbulence or other aspects of the wind over snow). Flow rates are probably on the order of a few millimeters per second and are likely to be confined to near-surface layers of snow. Observations of the mixing depth of aerosols and particulates in snow layers indicate that wind pumping is definitely effective in moving mass, but the magnitude of the effect of wind-pumping on heat transfer has yet to be demonstrated. In addition, it appears that near-surface and surface wind and melt crusts in the snow can effectively eliminate any wind-pumping by reducing the air permeability of the snow creating barriers in the form of impermeable wind on melt crusts that can effectively shut off all air movement.

Figure 14 The air permeability of snow. Again, there is a greater variation by snow type than by density. From Shimizu H (1970) Air permeability of deposited snow. Low Temperature Science, Series A, 1–32.

As neither wind-pumping nor buoyancy-driven convection are state properties of the snow, they pose difficulties when one is trying to model heat transfer in snow. Both processes depend on external conditions for their onset and strength, and they can transport anything from zero to several times the conductive heat flux, depending on the snow characteristics, the temperature structure in the snow, and the wind speed and direction.

Water, water vapor, CO_2 , methane, and aerosols and particulates are all transferred across a snow cover and the transfer process for each is complicated. In general, mass transfer is controlled by the air permeability of the snow, the surface topography of the snow cover (for wind-pumping), and the supply rate of particles, gases, or chemicals. As discussed previously, both diffusive and convective transport of air are possible, and the chemicals and gases move with the air. The air permeability of naturally occurring snow (Figure 14) ranges over two orders of magnitude. It is a major control on deposition and transfer rates, which vary widely with chemical species and environmental conditions. For aerosols, when the residence time of the air in the snow is greater than 15 seconds, the filter efficiency of the snow can be almost 100%.

Introduction

Modern numerical weather prediction (NWP) models represent the current state of the atmosphere using many millions of numbers. Despite the growing numbers of satellite and *in situ* observations, the state is often poorly determined by the observations alone. Accordingly, a data assimilation process in which the NWP model state is fitted to past and present observations has replaced early computer methods of producing an objective analysis by interpolating the observations. Under certain simplifying assumptions, the optimal assimilation is given by a sequential estimation method known as the Kalman filter, but this cannot be implemented in practice because it requires the manipulation of enormous covariance matrices. A variational approach of fitting the model state to observations is more practical, and has the advantage of being able to use observations nonlinearly related to the model state. Alternative methods using ensembles are being explored, while simpler methods are common for mesoscale systems.

Using Observations in NWP

Modern weather prediction is based on numerical forecast models that represent the atmosphere's variables (wind, temperature, pressure, moisture, cloud, etc.) on a set of levels from the surface to the stratosphere, and a horizontal grid (or equivalent spectral representation) capable of resolving weather systems. For instance, in 2002 the Met Office's global NWP model had 38 levels and a horizontal grid spacing of 60 km; it represents the atmosphere using 10^7 numbers. As available computer power doubles every few years, the size and complexity of models used increases correspondingly.

An illustration of the number of observations available to determine the initial state for a global forecast model is shown in [Table 1](#). In some places some variables are well observed, indeed some observation types are thinned before use, but in many places many variables are poorly determined by the observations. Thanks to advances in remote sensing technology, and in automation, the quality and coverage of observations is continuing to improve, but the requirements for NWP models are increasing as well – some areas and variables will remain relatively poorly observed.

In the days of manual forecasting, before computers, the process of determining the initial conditions from the observations was called weather map analysis. Early computer forecasting systems attempted to replicate this by interpolating between the observations to a regular grid, using a so-called objective analysis program. Because of the sparsity of observations, this approach does not meet the requirements of modern NWP for an accurate and detailed representation of all the atmosphere's variables; extra information must be used. NWP models are based on the physical equations describing the atmosphere's evolution, and hence encapsulate much of our prior knowledge about the atmosphere. Thus we use an NWP model as part of an efficient system to determine the atmospheric state from incomplete observations. This process is called data assimilation. It naturally gives a picture of the atmospheric state in the form needed to start an NWP forecast.

Data assimilation for NWP proceeds sequentially, in cycles. A model state at a particular time summarizes, in organized form, the information gleaned from all earlier observations. The NWP model is integrated forward to the times of the observations in the latest batch. This provides a background state, with which the new information is combined, to create a model state that is a new best estimate.

Table 1 Observations Used in Global Data Assimilation in October 2000

Observation group	Subgroup	Items used	Daily	Percentage used
Ground-based vertical profiles	TEMP	T , V , RH processed to model layer average	1200	97
	PILOT	As TEMP but V only	900	99
	PROFILER	As TEMP but V only (used from February 2001)	300	0 (65)
Satellite-based vertical profiles	TOVS	Radiances directly assimilated with channel selection dependent on surface, instrument, and cloudiness	54 000	11
	ATOVS		700 000	4
Aircraft (manual and automated)	AIREPS	T , V as reported with duplicate checking and blacklist	14 000	21
	ACARS AMDAR ASDAR		67 000	60
Satellite atmospheric motion vectors	GOES 8, 10	High resolution 'BUFR' IR winds	55 000	24
	Meteosat 5, 7	IR, VIS, and WV winds	9200	98
	GMS 5	IR, VIS, and WV winds	5200	93
Satellite-based surface	ERS-2	Wind vector retrievals (ambiguous winds from February 2001)	170 000	0
	SSM/I-13	In-house 1D-VAR wind speed retrieval (no moisture yet)	1 450 000	1
Ground-based surface	Land Synop	Pressure only (processed to model surface)	27 000	80
	Ship Synop	Pressure and wind	6000	90, 95
	Buoy	Pressure	9000	75

T , temperature; V , vector wind; IR, VIS, and WV winds, winds tracked from sequences of infrared, visible, and water vapor imagery.

Typical coverage maps are available at http://www.metoffice.com/research/nwp/observations/data_coverage/index.html. Only a small selection of high-density satellite observations are currently used; about 1.6×10^5 data are presented to the variational analysis.

Following the old manual terminology, this state is often called the analysis. It is used to start the NWP model forecast in the next cycle. If necessary, an initialization method is used to make sure each NWP forecast starts smoothly. It is important to realize that the NWP model is key to the process; the information in the model state from earlier observations is much more important than that in any single batch.

Statistical Estimation Theory

Statistically optimal methods of combining the new observations with the model forecast depend on knowledge of the error probability distribution function of each. The optimal method is simplest when the error distributions are Gaussian, with mean zero. In reality, most observations can suffer from occasional gross errors, due to instrument or communications failures, and some types of observation can suffer from systematic biases. Usually, some quality control and bias correction are done prior to the main assimilation step, in which case the remaining observations may be assumed to have the desired Gaussian distribution. Less theoretically, one can see that a quality control procedure is essential to avoid using the corrupted observations, and that proper calibration of observations will improve their utility. A Gaussian distribution can be completely described by a covariance matrix. Most sources of observational errors are independent, making covariances between them zero; that is, for most observations the error covariance matrix is diagonal.

The errors in the background state are harder to characterize, since during the forecast process errors spread and grow dynamically, leading to significant covariances in space and

time, and between variables. One practical approach, used in so-called statistical interpolation or optimal interpolation algorithms, is to model the background error covariances using structure functions, assuming them stationary, homogeneous, and isotropic. Denoting the model background state by vector $\mathbf{x}^b$, the observations by vector $\mathbf{y}^o$, the linear operator for calculating estimates of the observed values from a model state by $\mathbf{H}$, the observational error matrix by $\mathbf{R}$, and the background error covariance matrix by $\mathbf{B}$, the optimal analysis ($\mathbf{x}^a$) and its error covariance ($\mathbf{A}$) are given by eqns [1] and [2].

$$\mathbf{x}^a = \mathbf{x}^b + \mathbf{B}\mathbf{H}^T(\mathbf{H}\mathbf{B}\mathbf{H}^T + \mathbf{R})^{-1}(\mathbf{y}^o - \mathbf{H}\mathbf{x}^b) \quad [1]$$

$$\mathbf{A} = \mathbf{B} - \mathbf{B}\mathbf{H}^T(\mathbf{H}\mathbf{B}\mathbf{H}^T + \mathbf{R})^{-1}\mathbf{H}\mathbf{B} \quad [2]$$

In principle, under the assumption that errors are small enough to be propagated by the linearization of the NWP model, it would be possible to calculate the background error covariances explicitly from the analysis error covariances of the previous cycle. This is the approach followed in the Kalman filter assimilation method, which for known Gaussian errors and a linear system is the theoretically optimal sequential assimilation method. However, because of the size of NWP models, it is not feasible in practice even to store the full matrices $\mathbf{A}$ and $\mathbf{B}$, let alone to propagate them in time.

Although the basic methods for combining imperfect observations have been understood since Gauss in the early nineteenth century, we are not able to apply even these in a truly optimal way since they require error covariances that we cannot know accurately, and that we could not manipulate on available computers if we did know them. Added complications are the gross errors in observations, which make their error distributions non-Gaussian, and the nonlinear, chaotic

nature of the forecasting equations, which makes background errors non-Gaussian. Theory for handling non-Gaussian probability distribution functions exists, but its application to this size of problem is even less feasible. Practical data assimilation methods for NWP have to use approximate methods, applying the available computer power to those parts where our knowledge justifies it.

Variational Assimilation

Rather than interpolating from observations to a grid, assimilation is best thought of as an inverse method, fitting the model state to scattered data. In variational assimilation, observation operator algorithms are applied to a model state to predict the observations. Any observations can be used, as long as the observation operator to predict their values is a well-behaved, linearizable function of the model values. For instance, it is straightforward to use satellite observed radiances for frequency channels emitted or absorbed by the atmosphere: the observation operator is a radiative transfer calculation of the upward radiances. We represent the observation operator by function H . These predictions are compared with the actual values, and a penalty measuring the misfit is calculated. This is added to a measure of the misfit from the background, to give a total penalty function (eqn [3]).

$$J = \frac{1}{2}(H(\mathbf{x}) - \mathbf{y}^o)^T \mathbf{R}^{-1}(H(\mathbf{x}) - \mathbf{y}^o) + \frac{1}{2}(\mathbf{x} - \mathbf{x}^b)^T \mathbf{B}^{-1}(\mathbf{x} - \mathbf{x}^b) \quad [3]$$

The model state ($\mathbf{x}$) is varied until the minimum of the penalty function is found. Since the terms in the penalty function are weighted using the appropriate error covariance estimates, the variational approach is equivalent to the statistical estimation discussed above (for linear H). However, it can be extended to use nonlinear observation operators, using satellite radiance observations, for instance, and to perform implicit quality control, by allowing for nonnormal distributions of observational errors. To find the minimum in a reasonable number of iterations, a descent algorithm is used requiring the vector of partial derivatives of J with respect to the elements of $\mathbf{x}$ as in eqn [4], where $\mathbf{H}^T$ is the transpose of the linearization of H , often called the adjoint.

$$\left(\frac{\partial J}{\partial \mathbf{x}}\right)^T = \mathbf{H}^T \mathbf{R}^{-1}(H(\mathbf{x}) - \mathbf{y}^o) + \mathbf{B}^{-1}(\mathbf{x} - \mathbf{x}^b) \quad [4]$$

In practice, further steps are needed to make the minimization problem tractable. The background error covariance cannot be explicitly represented as a matrix: it would be too large, and inverting it is even more impracticable. One approach is to express the penalty function in terms of a transformed model state, for which the background term is simpler. The gradient calculation then also requires the adjoint of this transformation, as well as that of the observation operators.

If the observations in a batch are treated as simultaneous, the resulting algorithm is called 3D-Var. The observation operator procedure of calculating model estimates of the observations can be generalized to include a forecast model

Figure 1 Schematic diagram of 4D-Var. The observed values $\mathbf{y}^o$ are forecast from the model state $\mathbf{x}$ – this process is represented by the dotted lines and by H in eqn [3]. The adjoint of this forecast is used in eqn [4] to determine how to vary $\mathbf{x}$, iterating until the best fit that minimizes J is found.

integration. (If we redefine H to include both the forecast and the observation operator, then the equations above are unaltered.) The adjoint of the forecast model is then needed for the gradient calculation. Each iteration of the minimization's descent algorithm requires a forward integration of the forecast model over a period spanning the observations, and a backward integration of the adjoint model. Since several tens of iterations are generally needed, this 4D-Var algorithm is computationally expensive. 4D-Var is capable of properly assimilating observations distributed in time; for instance, it can use observed tendency information in a dynamically consistent way (Figure 1). Under certain simplifying assumptions, 4D-Var gives the same analysis as a Kalman filter.

Quantifying Uncertainty: Ensembles

A drawback of 4D-Var is that it does not readily provide estimates of the analysis error covariances ($\mathbf{A}$); evaluation using eqn [2] is impracticable. These are required for an algorithm such as the Kalman filter to calculate background error covariances for the next cycle. Without these dynamically varying covariances it is not possible optimally to link the cycles processing batches of observations.

More directly relevant to users of NWP is the desire for an estimate of possible errors in forecasts. The value of forecasts to decision makers is greatly enhanced if the inherent uncertainty can be quantified. This is particularly true of severe weather, which can cause such damage to property and loss of life that precautions may be well advised even if the event is unlikely but possible. Probabilities are a natural way of expressing uncertainty. A range of possible outcomes can be described with associated probabilities, and users can then make informed decisions allowing for their particular costs and risks.

It is impracticable to represent the covariances explicitly as matrices as in the Kalman filter; they are too large to store and manipulate. An alternative approach is to represent the error probability distributions by an ensemble of model states. Because the atmosphere is chaotic, a few patterns of error grow

rapidly, but most do not grow. So it is plausible that a reasonable sample of model states could represent the important components of error covariance matrices, despite having many fewer degrees of freedom. Research is under way into the 'Ensemble Kalman filter' using this approach. Several hundred slightly different analyses are made, and the covariances of forecasts from them are used to approximate any required background error covariances, instead of manipulating and forecasting huge error covariance matrices. The ensemble approach is already well established to forecast uncertainty in medium-range forecasting, but is not yet proven in practice for data assimilation.

Mesoscale Assimilation

Forecasts extending from zero out to about 6 h are based upon a more observations-intensive approach and are referred to as 'nowcasts'. Traditionally, nowcasting has focused on the analysis and extrapolation of observed meteorological fields, with a special emphasis on mesoscale fields of clouds and precipitation derived from satellite and radar. For better handling of developing weather systems, there is increasing emphasis on using NWP for these scales. There are important practical constraints on such a system: it has to assimilate frequent high-resolution data into a high-resolution model, and it has to deliver short-period forecasts promptly, before their utility has expired. To achieve this, usually rather simpler assimilation methods have been employed. One method is to nudge in the observations over a period of time into the

forecast model; for instance, if the observations show rainfall, then the model's temperature variables can be affected by the corresponding latent heating. Correctly tuned, such methods can induce the model state to approach that of the atmosphere.

As computer power increases, it is becoming possible to consider variational methods for assimilating such data. Complicated observation operators, and their adjoints, are needed for predicting precipitation. The variational method tries find a model state that fits the observations to within their estimated error. This potentially can make much better use of cloud and precipitation data.

Synopsis

This article introduces the algorithm of ensemble-based data assimilation (EDA) and the main issues in its application to atmospheric sciences. EDA is drawing increasing attentions in data assimilation community mainly due to its flow-dependent background error covariance determined using a short-range ensemble forecast and ease of implementation. Many types of EDA have been applied with different models at different scales in both research and operational or quasi-operational communities. Various aspects involved in EDA are discussed including observations, ensemble initialization, sampling error, covariance inflation and localization, model error, verification, nonlinearity and non-Gaussian errors, intercomparison, and hybrid with variational schemes.

Introduction

The accuracy of weather forecasts is mainly determined by the accuracy of numerical weather prediction (NWP). NWP produces the time evolution of basic meteorological variables including wind, pressure, temperature, moisture, and other hydrometeors based on basic physical laws. Its accuracy depends critically on the qualities of the initial conditions and the forecast model. The initial conditions of an NWP model are usually produced through data assimilation, a procedure that aims to estimate the state and uncertainty of the atmosphere as accurately as possible by combining all available information (including both previous model forecasts and current observations, and their respective uncertainties). Data assimilation methods update the model forecasts through the error covariance of the model forecast between different grid points and variables.

Data assimilation is typically performed through one of the two methods. The first method is variational method, which finds an analysis that has a minimum misfit to the observation and the background forecast (or the first guess). Two main methods in this category are three-dimensional (3DVar, three dimensions in terms of space, Barker et al., 2004) and four-dimensional variational methods (4DVar, three dimensions in terms of space plus one in terms of time, Le Dimet, 1982). Variational methods generally produce their background error covariance using a period of forecast differences between different lead times (Barker et al., 2004; Xiao and Sun, 2007), thus is isotropic and stationary.

The other approach is sequential data assimilation. A theoretically optimum sequential method is the Kalman filter, which assumes Gaussian errors and a linear system. Kalman filter is named as extended Kalman filter for nonlinear models. Since the extended Kalman filter explicitly propagates the background error covariance, it is not practical for large-dimensional systems like the atmosphere or the ocean. Evensen (1994) proposed the ensemble Kalman filter (EnKF) that estimates the background error covariance with a short-term ensemble forecast. The EnKF is drawing increasing attentions in data assimilation community. Since its first application in atmospheric sciences (Houtekamer and

Mitchell, 1998), many types of EnKFs have been applied with different models at different scales (Lorenc, 2003; Houtekamer and Mitchell, 2005; Hamill, 2006; Ehrendorfer, 2007; Meng and Zhang, 2010). The potential of using ensemble-based data assimilation (EDA) is also being explored in several operational meteorological centers. A global- (regional) scale EnKF has been put into operational practice at the Canadian Meteorological Center (Italian Weather Service). There are a few quasi-operational limited area model (LAM)-EnKF systems such as those performed at the University of Washington, the Pennsylvania State University, and the National Center for Atmospheric Research. This article aims to give a brief introduction to the EnKF algorithm and main issues in its application to atmospheric sciences.

The Concept of the EnKF

The EnKF has two steps: an analysis step and a forecast step (Figure 1). The analysis step in the standard EnKF proceeds according to the classical Kalman filter equations with the required sample means and covariances:

$$\mathbf{x}_i^a = \mathbf{x}_i^b + \mathbf{K}(\mathbf{y}_i^o - \mathbf{H}\mathbf{x}_i^b), \quad \text{for } i = 1, \dots, n \quad [1]$$

$$\mathbf{K} = \mathbf{P}^b \mathbf{H}^T (\mathbf{H} \mathbf{P}^b \mathbf{H}^T + \mathbf{R})^{-1} \quad [2]$$

Figure 1 Schematic diagram of the flow chart of the EnKF. The meaning of the various variables is referred to the text. EnKF, ensemble Kalman filter.

$$\mathbf{P}^b = \frac{1}{n-1} \sum_{i=1}^n \left[\left(\mathbf{x}_i^b - \bar{\mathbf{x}}^b \right) \left(\mathbf{x}_i^b - \bar{\mathbf{x}}^b \right)^T \right] \quad [3]$$

$$\mathbf{P}^a = \frac{1}{n-1} \sum_{i=1}^n \left[\left(\mathbf{x}_i^a - \bar{\mathbf{x}}^a \right) \left(\mathbf{x}_i^a - \bar{\mathbf{x}}^a \right)^T \right] \quad [4]$$

where, $\bar{\mathbf{x}}^b$ and $\bar{\mathbf{x}}^a$ are the sample mean values of the forecast and the analysis ensemble. The analysis state vector, $\mathbf{x}_i^a$ for the i th ensemble member is obtained by adding to the background state vector, $\mathbf{x}_i^b$, a weighted difference between observations, $\mathbf{y}^o$, and the background state vector projected to observation space through an observation operator, H . $\mathbf{P}^a$ and $\mathbf{P}^b$ are the analysis and background error covariance respectively, which are approximated in the EnKF by the respective ensemble covariance. $\mathbf{K}$ is the Kalman gain, which takes into account the observation error, $\mathbf{R}$, and the background error covariance, $\mathbf{P}^b$ in determining the extent to which observations are weighted relative to the background. $\mathbf{H}$ and $\mathbf{H}^T$ are the tangent linear and adjoint versions of H , respectively. Tangent linear means the linearization about a time or space-varying trajectory of a nonlinear operator, which gives the evolution of the first-order perturbation of a nonlinear vector. In the EnKF, $\mathbf{P}^b \mathbf{H}^T$ and $\mathbf{H} \mathbf{P}^b \mathbf{H}^T$ are calculated using the sample covariance and thus $\mathbf{H}^T$ and $\mathbf{H}$ are not explicitly needed.

Given the analysis ensemble, the forecast step simply involves forecasting each member forward from time t to $t + \Delta t$ when the next observations are available:

$$\mathbf{x}_i^b(t + \Delta t) = M(\mathbf{x}_i^a(t)), \quad \text{for } i = 1, \dots, n \quad [5]$$

where M is a nonlinear model. The ensemble-based algorithm asymptotically approaches the Kalman filter in the limit of a large ensemble and Gaussian error distributions.

The EnKF has many variants. Based on the method for generating the analysis ensemble, an EnKF can be characterized as stochastic, where the analysis ensemble is obtained with the Kalman gain and randomly perturbed observations, or deterministic, where the analysis ensemble is created by transforming the forecast ensemble without perturbing the observations. Due to the large dimension of the model state vector and the large number of observations needed in the LAM-EnKF scenario, various algorithms of the LAM EnKF have been proposed to improve computational efficiency. The most commonly employed deterministic method has the form of ensemble square root filters (EnSRFs) such as the serial EnSRF, the ensemble transform Kalman filter, and the ensemble adjustment Kalman filter.

Observations

Different observing platforms or different formulations of the same observations may have different impacts on the EnKF performance. For example, radiosonde observations have been found to have the largest impact on regional-scale analyses and forecasts. Due to errors coming from the difference between the real and the model terrain height and uncertainties in the parameterization of boundary layer and land surface physical processes, surface observations have been a big challenge. The analysis and forecast error may benefit from removing the bias and reducing the representativeness error by assimilating only those data whose locations have a terrain height that matches

the model one, and removing the bias of surface wind and temperature before assimilation. However, surface data assimilation may have very limited impact on the levels above the surface and on the time length of the forecast into the integration.

Besides the conventional radiosonde and surface observations, remotely sensed observations are drawing more and more attention. Doppler radars such as Doppler on Wheels, Weather Surveillance Radar 88 Doppler, and airborne radars have sufficient temporal and spatial coverage to fully observe convective clouds. The effectiveness of using the EnKF to assimilate Doppler radar velocities for supercell storms was first demonstrated in [Snyder and Zhang \(2003\)](#) and with real-data in [Dowell et al. \(2004\)](#). An X-band radar network that was deployed by the National Science Foundation Engineering Research Center for Collaborative Adaptive Sensing of the Atmosphere has been helpful in improving the analysis and forecast of convective system, which supports convective-scale warn-on-forecast operations. Airborne Doppler radar radial-velocity observations have also been successfully assimilated in real time for a hurricane prediction model ([Zhang et al., 2011](#)). The EnKF system has demonstrated promising performance, especially on hurricane intensity forecasts, through experiments over 61 applicable The National Oceanic and Atmospheric Administration (NOAA) P-3 airborne Doppler missions during the 2008–10 Atlantic hurricane seasons ([Figure 2](#)). The mean absolute intensity forecast errors initialized with the EnKF analysis of the airborne Doppler velocities at the 24–120-h lead forecast times were 20–40% lower than the National Hurricane Center's official forecasts issued at similar times. Radar reflectivity has been shown to be less effective than Doppler radial velocity. The likely non-Gaussian error distribution, weak cross-correlations between state variables, inherent small-scale variability, and strong dependence of these quantities on the accuracy of model microphysics schemes appear to be the main limiting factors. Nevertheless, the assimilation of differential reflectivity, Z_{dr} , reflectivity difference, Z_{dp} , and specific differential phase, K_{dp} , beyond radar reflectivity and/or radial velocity may improve storm analysis ([Jung et al., 2008](#)). Moreover, the assimilation of even the echo-free radar observations, defined as radar reflectivity below a threshold value of 5 dBZ, sometimes may effectively suppress spurious convection ([Aksoy et al., 2009](#)).

Radar data need to be vigorously preprocessed to have a consistently positive impact. With large volumes of radar observations recorded at a much higher resolution than the forecast model grid spacing, significant data thinning may be necessary. The process of combining multiple observations into one high-accuracy 'super' observation is often referred to as 'superobbing.' This data preprocessing procedure has been implemented operationally on the NOAA hurricane reconnaissance aircraft that allows for more efficient real-time transmission of airborne radar observations to the ground ([Zhang et al., 2011](#)). Assimilating airborne Doppler radar data in storm-relative coordinates under a simultaneity assumption may produce a better kinematic tropical cyclone (TC) structure and a slower error growth ([Aksoy, 2013](#)). This method translates the observations of the whole flight to a common storm center by maintaining their relative positions at the time of their actual sampling, then randomly distributed to different cycles to achieve a more homogenous data coverage among data assimilation cycles.

Figure 2 (a) The Weather Research and Forecasting model (WRF) model domain configuration and TC tracks with NOAA airborne Doppler radar mission. The outer domain is fixed for all cases, while the three inner domains are centered at the storm's center at the initial time and movable flowing model vortex center during the forecast. Fourteen storm tracks are colored lines with storm intensity. With blue dots circled with red, 61 missions of NOAA airborne Doppler radar observation are marked. All the storms and case numbers are listed on the right top. Also shown are the mean absolute forecast error averaged over 50 samples homogenized by all 61 airborne Doppler missions during 2008–10 for The National Hurricane Center (NHC) Official forecast ('OFCL,' solid cyan line), The Geophysical Fluid Dynamics Laboratory (GFDL) hurricane model ('GFDL,' green line), The Hurricane Weather Research and Forecasting model ('HWRF,' dark blue line), and the WRF deterministic forecast in 4.5-km resolution initialized with EnKF analysis ('EnKF,' red line) after making the samples homogeneous for all five forecasts for (b) the track position error (km) and (c) the 10-m maximum wind speed error (knots) with simple bias correction

In addition to radars, the assimilation of satellite observations and/or satellite-derived products is also a hot topic. Multivariate specific humidity retrieved from the Atmospheric Infrared Sounder (AIRS), satellite-derived atmospheric motion vectors, and temperature and mixing ratio profiles derived from the AIRS instrument on board the *Aqua* satellite have been shown beneficial for weather analysis and forecast (Jones and Stensrud, 2012). However, direct assimilation of satellite radiance with the EnKF is still in its infancy. Challenging Minisatellite Payload radio occultation refractivity has been found to be beneficial in regions where conventional high-quality observations are sparse. Liu et al. (2012) reported a better performance in assimilating The Advanced Microwave Sounding Unit (AMSU) radiance than without radiance assimilation for the track and intensity forecast of five TC events in 2008 over the Atlantic Ocean with EnKF. A track error reduction of up to 16% was achieved for forecasts beyond 36 h largely due to the improvement in the representation of TC environments. Results also showed more benefit when both radiances and satellite winds than when radiances alone were assimilated. Many issues remain to be explored in satellite radiance assimilation such as observation bias correction.

Besides the aforementioned *in situ* and remotely sensed data, some special synthesized object-oriented observations, such as the vortex position of tropical cyclones, can also be easily assimilated by the EnKF and have been demonstrated to be helpful in improving hurricane forecast ability.

Ensemble Initialization

How to create an initial ensemble that reflects the uncertainty of the initial analysis is an important and critical issue. Global EnKFs typically use random samples from a climatological error distribution, or generate perturbations from a preexisting 3D/4DVar system. The LAM-based EnKF may be initialized from an existing global or larger scale ensemble or by using one of the methods used for the global model if a global ensemble forecast is not readily accessible. The generation of the initial ensemble for convective-scale EnKF systems remains an open question due to the lack of accurate error statistics. For many convective-scale applications, Gaussian noises are added to a horizontally uniform background (sounding) for all state variables (e.g., Snyder and Zhang, 2003).

Compared to the initial condition uncertainties, a proper representation of boundary uncertainties may have a larger impact on the LAM EnKF. A lack of sufficient ensemble spread on the lateral boundaries may propagate inward and lead to filter divergence. Filter divergence means that the ensemble mean deviates further and further away from the truth due to the underestimated variance of the forecast ensemble, which results in more weight being given to the prior (model forecast) than to the observations. Boundary perturbations can be

for all forecasts except for OFCL. The red numbers on the x axis of (c) indicate the sample size for the homogeneous comparison. Adapted from Zhang, F., Weng, Y., Gamache, J.F., Marks, F.D., 2011. Performance of convection permitting hurricane initialization and prediction during 2008–2010 with ensemble data assimilation of inner-core airborne Doppler radar observations. *Geophysical Research Letters* 38, L15810. <http://dx.doi.org/10.1029/2011GL048469>.

generated using the same methods as ensemble initialization described above.

Sampling Error, Covariance Inflation, and Localization

Due to computational constraints, only a limited ensemble size can be afforded in the EnKF, which will result in sampling errors. The number of members sufficient for the EnKF to minimize the impact of sampling errors still remains an open question. Until now, most published EnKF studies use an ensemble size of 30–100. Due to the limited ensemble size, the EnKF generically suffers from a rank-deficiency problem in which only a part of the phase space can be spanned by the ensemble. As a result, the ensemble spread tends to be systematically underestimated.

The underestimation of ensemble spread is commonly treated by covariance inflation through multiplicative or additive scaling, or covariance relaxation. Additive covariance inflation adds a set of ensemble perturbations that can reflect forecast uncertainty to the forecast ensemble, where multiplicative covariance inflation is achieved by multiplying all ensemble perturbations before or after the EnKF analysis with a constant slightly larger than 1. However, multiplicative covariance inflation with a spatially constant inflation factor may cause a model to become unstable due to excessive spread in data-sparse regions. A Bayesian algorithm was proposed using a spatially and temporally varying adaptive inflation factor for each element of the model state vector (Anderson, 2009). Another approach is the covariance relaxation method through relaxation of the final analysis perturbations to the prior forecast (Zhang et al., 2004). The relaxation method only inflates the variance at grid points that are updated by observations, thus avoiding the overinflation deficiency of the conventional inflation method.

Besides the underestimation of ensemble spread, sampling errors in the EnKF may also cause unphysical, distant correlations and subsequently spurious analysis increments. The most commonly used approach for reducing distant spurious correlations is through covariance localization. Covariance localization is often implemented by multiplying a Gaussian shape function that decreases smoothly from one at the observation point to zero at a certain distance from the observation. The impact of an observation is thus confined only within a limited distance. This distance is usually called the radius of influence (ROI). Localization may not only decrease spurious distant correlation, but also reduce the computational cost and alleviate the rank-deficiency problem due to the limited ensemble size. The value of ROI may depend on ensemble size, observation type and density, model error and resolution, as well as the characteristic scales of the underlying dynamic system. For examples, a horizontal ROI of 1000–2000 (60–150) km is often used for standard radiosonde (surface) observations, while a much smaller ROI ranging from several to hundreds of kilometers is often used for radar observations. It was once suggested that the ROI should be two to three times the forecast error scales (Lorenc, 2003). Zhang et al. (2009a) proposed a successive covariance localization (SCL) technique in which a larger ROI is used to assimilate a relatively small subset of observations in the coarser domains, while a smaller ROI is used to assimilate higher density

observations in the inner domains. They found clear advantages of using the SCL method over using single ROIs in the assimilation of dense radar observations for rapidly developing landfalling hurricanes. The vertical ROI is sometimes set to the depth of the atmospheric model for conventional observation assimilation or vertical covariance localization is not performed at all. Besides ROI, the selection of a covariance localization function may also be important. The most widely used covariance localization is the fifth-order correlation function of Gaspari and Cohn (1999). The choice of localization function may become more complicated for observations that have complex spatial, temporal, and physical attributes or with an unknown relation with the state variable.

While accounting for sampling error, covariance localization may cause imbalance when one observation is selected to update the state vector at one grid point, but not selected for a neighboring grid point (Lorenc, 2003). Consequently, covariance localization may produce analyses with weaker flow balance and stronger divergence, which may result in inaccurately balanced background error statistics. Methods used to reduce imbalance in large-scale models such as applying a digital filter (e.g., Lynch and Huang, 1992) or covariance localization performed in the stream function–velocity potential rather than the wind component space (Kepert, 2009).

Model Error

Since the EnKF depends critically on the quality of the first guess and the forecast error covariance estimated from a short-term ensemble forecast, the presence of model error may lead to poor filter performance and even filter divergence. Model error can result from inadequate parameterizations of subgrid-scale physical processes, numerical inaccuracy, truncation error, ill-defined boundary conditions, or other random errors. The presence of model error often results in both a large bias in the ensemble mean and too little spread, which may ultimately cause the ensemble forecast to fail.

There are several ad hoc approaches that have been used to account for model error in the context of the EnKF such as covariance inflation, bias correction, the use of multimodel or multiphysics ensemble, and simultaneous state and parameter estimation. Additive covariance inflation has been shown to be effective in improving the performance of the EnKF. Though most statistical data assimilation methods assume that the model forecast (or first guess) is unbiased, this is rarely the case. Over the past decade, there has been an increasing amount of evidence demonstrating the advantages and effectiveness of using multimodel ensembles (over single-model ensembles) to account for model error in the prediction system (e.g., Krishnamurti et al., 1999; Weisheimer et al., 2009). However, given technical implementation difficulties associated with inherent differences in model numerics, dynamical coordinates, and/or (prognostic) state variables among different forecast models, multimodel ensembles have not been used for the EnKF. Since a considerable part of the model error comes from the parameterization of subgrid-scale physical processes, a more practical approach is to use a variety of physical parameterization schemes available in the same forecast model or a variety of values of some parameters in a particular scheme for different members to account for model uncertainties. This

multiphysics ensemble approach has been shown to be effective in accounting for model error in both global and mesoscale ensemble forecast systems (Meng and Zhang, 2007; Fujita et al., 2007), likely through improved ensemble mean estimates, an increased ensemble spread, and a more effective background error covariance. With the development of more sophisticated physical schemes, how to assign weights of various available schemes in the ensemble may become a critical issue. Besides, stochastic kinetic energy backscatter (Shutts, 2005) has been used as more physically based parameterization of model error (Leutbecher, 2007).

The uncertainty in physical parameterization schemes is closely related to the uncertainty of its parameters. Almost all parameters of subgrid physical parameterization schemes are empirical, due to a lack of direct observations, and could therefore have large and unknown uncertainties. Parameter estimation is a technique in which the EnKF is used to estimate these parameters by treating them as additional model variables and updating them through data assimilation. This technique may help improve the performance of the EnKF via a model error correction. Since there are no direct observations or physical evidence describing the variability of various parameters, the generation of a realistic initial ensemble for the estimated parameter is even more difficult than for standard state variables. Furthermore, not all parameters can be successfully estimated. The performance of a parameter estimation algorithm depends on the correlation between the parameter and model variables and is closely related to the EnKF configuration. Parameter estimation performance using the EnKF is also closely associated with the number of simultaneously estimated parameters. It was found that the estimation of a single parameter is very effective in improving the performance of the EnKF. Increasing the number of estimated parameters inevitably leads to a decline in the improvement from parameter estimation (Aksoy et al., 2006).

Verification

The realism of the analysis and forecast ensembles is usually verified using rank histogram (Anderson, 1996; Hamill and Colucci, 1997). A rank histogram describes the extent to which an ensemble encompasses the verifying data by ranking the verifying data in the sorted ensemble. The reliability of an ensemble can be diagnosed by the shape of its rank histogram. A flat shape implies that the observation can be taken as a random member of the ensemble, and consequently the ensemble is reliable. A U-shape suggests that the ensemble spread is insufficient, while a reversed (upside down) U-shape indicates that the ensemble spread is too large.

Grid point-based root mean square error (RMSE) of different variables integrated over the whole model domain is usually used for verification for the analysis and/or forecast ensemble means of the EnKF. Due to a lack of dense, conventional mesoscale observations, verification of the LAM EnKF can be more difficult than verification of larger scale prediction systems, especially for radar data assimilation. One way is to compare the analysis and/or forecast against radar observations that are not assimilated, but saved specifically for assessment. The equitable threat score can be used to verify the result in

terms of radar reflectivity. An alternative metric that is more pattern-based is the reflectivity correlation coefficient between the observed and simulated reflectivity in observation space. For severe weather systems, such as hurricanes, how to choose an appropriate error metric is still an open question. Since a small displacement of a storm center may result in a substantially large RMSE of wind, performance could be better assessed using feature-based verification.

Nonlinearity and Non-Gaussian Errors

Though the EnKF can be used in nonlinear and non-Gaussian systems, the performance of the EnKF may be affected and ultimately limited by these two characteristics. Variants of algorithms for highly nonlinear and non-Gaussian systems have been proposed, such as the particle filter, the particle Kalman filter, the iterative EnKF and extended Kalman filter, morphing methods, 'Running in place,' and the 'quasi-outer loop.' While these methods have been applied for simple models, many have not been tested on high-dimensional systems, such as full-physics atmospheric models. How to construct proper algorithms to deal with high nonlinearity and non-Gaussianity awaits further efforts.

Intercomparison and Hybrid with Variational Schemes

Despite many of the challenging issues discussed in the previous sections, there are several appealing advantages of the EnKF in comparison to the variational data assimilation techniques. These advantages include: (1) The background error covariance is flow-dependent, which reflects the errors of the day; (2) The model and observation operator can be nonlinear; (3) It provides not only the best estimation of the state, but also the associated flow-dependent uncertainty; therefore, it can be seamlessly coupled with ensemble forecasting; (4) There is no need to code a tangent linear or adjoint model; (5) It is easier to account for model error due to its use of an ensemble forecast; and (6) The ensemble members can be run simultaneously, making it easy to parallelize.

Many studies have shown that the EnKF generally compares favorably with 3DVar (Meng and Zhang, 2008a,b) and 4DVar (Caya et al., 2005). Zhang et al. (2013) found that the advantage of the EnKF over both 3DVar and 4DVar becomes increasingly more after 36-h forecast time for all prognostic variables, while the EnKF moisture forecast field is superior to both 3DVar and 4DVar at all lead times despite fitting less closely to the observations at the analysis time.

Both the EnKF and variational method have their own advantages and disadvantages. The EnKF benefits from its flow-dependent background error covariance but suffers from rank deficiency, while the variational technique has advantages in its analysis algorithm. The variational approach can more efficiently assimilate large numbers of observations and apply physical constraints on the solution when minimizing the cost function, however, it is limited by the use of a static background error covariance matrix. Instead of settling on one particular method, more and more efforts are devoted to the

Figure 3 Comparison between WRF-based 3DVar, 4DVar, EnKF, E3DVar, and E4DVar in terms of domain-averaged root mean square errors averaged over all 59 WRF forecasts from June 2003 for each Data Assimilation (DA) experiment at forecast lead times from 0 to 72 h evaluated every 12 h for (a) U (m s^{-1}), (b) V (m s^{-1}), (c) T (K), and (d) Q (g kg^{-1}). 3DVar, three-dimensional variation; 4DVar, four-dimensional variation; EnKF, ensemble Kalman filter. Adapted from Zhang, F., Zhang, M., Poterjoy, J., 2013. E3DVar: coupling an ensemble Kalman filter with three-dimensional variational data assimilation in a limited-area weather prediction model and comparison to E4DVar. *Monthly Weather Review* 141, 900–917. <http://dx.doi.org/10.1175/MWR-D-12-00075.1>.

hybridization of the two approaches. A two-way coupled assimilation scheme benefits from using the state-dependent uncertainty provided by the EnKF, while taking advantage of the variational method from data assimilation algorithm. The EnKF/3DVar hybrid system of The Global Forecasting System (GFS)/The National Centers for Environmental Prediction (NCEP) has been showing consistently better TC track forecast than the operational Gridpoint Statistical Interpolation. A hybrid of EnKF with 4DVar is regarded as one of the most advanced and most promising (as well as most computationally and technically demanding) data assimilation methods in both the research and operational communities. Zhang et al. (2013) demonstrated that EnKF/4DVar produced considerable improvements over EnKF/3DVar at forecast lead times of 1–2 days before they converged to similar results at longer lead times (Figure 3). Both EnKF/3DVar and EnKF/4DVar produced considerably better forecast than stand-alone 3DVar and 4DVar methods that relied solely on static background error covariance.

It is important to bear in mind that a hybrid system will likely inherit issues or complexity from the component systems such as the rank-deficiency problem in the EnKF and the use of an outer loop in 4DVar. More efforts are needed to tackle these issues in the future. Considering the encouraging results obtained by coupling the EnKF with variational methods, several major operational NWP centers have already started testing or implementing such approaches in their global data assimilation systems such as Environment Canada, Météo-France, the European Center for Medium-Range Weather Forecasts, UK Met, and NCEP. Similar efforts for limited area data assimilation systems have not been reported.

Introduction

The atmosphere is a complex dynamical system with many degrees of freedom. In numerical weather prediction, the state of the atmosphere is described by the spatial distribution of wind, temperature, specific humidity, liquid water content, and surface pressure. The mathematical differential equations used to predict the system's time evolution include Newton's laws of motion and the laws of thermodynamics. Numerical weather prediction models predict the time evolution of the atmospheric state by solving the system equations numerically.

A deterministic forecast is a single integration of the system equations. The practical usefulness of a single deterministic weather forecast is limited by the day-to-day variability in its accuracy. This variability is partly associated with fluctuations in the predictability of the atmospheric flow, with predictable states (i.e., flows characterized by a slow amplification of initial errors) alternating with unpredictable states (i.e., flows characterized by a fast amplification of initial errors).

Ensemble systems are practical tools designed to assess the predictability of the daily atmospheric flow. More generally, they can be used to predict the time evolution of the probability density function (PDF) of forecast states. They can be used, for example, to predict the probability of intense rainfall or cold temperatures over the Euro-Atlantic region (Figure 1).

Ensemble systems should be designed to simulate the effect of all sources of forecast errors. In particular, they should simulate the effect of uncertainties in the knowledge of the initial state of the system and the effects of the approximations made in numerical weather prediction models.

Ensemble systems have been operational since 1992 at the European Centre for Medium-Range Weather Forecasts (ECMWF) in the United Kingdom and at the National Centers for Environmental Prediction (NCEP) in the United States, and since 1995 at the Meteorological Center of Canada (MSC). These three ensemble systems have been designed to estimate the forecast PDF in the short- and medium-forecast range, i.e., for up to 14 days. Beside this operational activity, many international centers, universities, and national and regional meteorological centers have been involved in research and experimental activities in this field. It should also be mentioned that experimental ensemble systems are currently under development and are tested for seasonal time scales.

Despite that fact that most of the examples and of the discussions reported here are based on results obtained during the past years by the operational medium-range ensemble systems, most of the discussions can be applied to seasonal ensemble systems.

Numerical Weather Prediction

In numerical models, the state of the atmosphere is described for a finite number of vertical levels and at a series of grid points

by a set of state variables such as temperature T , velocity v , specific humidity and cloud liquid content q , and surface pressure p . In other words, the state vector y of the system is defined by (T, v, q, p) for all vertical levels and all grid points. The phase space of the system is the N -dimensional space defined by the (T, v, q, p) coordinates.

The system attractor is defined by the set of past, present, and future atmospheric states $y(t)$. For each time t , a unique point on the system attractor identifies the state of the atmosphere. The time evolution of atmospheric states during subsequent times $t_0 < t < t_1$ between the initial time t_0 and the final time t_1 , is represented by the set of points that described the system orbit between t_0 and t_1 (Figure 2).

The mathematical differential equations describing the atmospheric motions include Newton's laws of motion in the form 'acceleration equals force divided by mass', the laws of conservation of mass and energy, and the laws of thermodynamics. These equations, written in terms of the state variables y , can be approximated with a set of algebraic difference equations for the tendencies (i.e., for the variations in time) of the state variables.

These equations include parameterization schemes that simulate the effects of physical processes such as radiative transfer, turbulent mixing, orographic forcing, and moist processes. The parameterization of these physical processes is probably one of the most difficult and uncertain areas of weather modeling.

Schematically, the equations of motion defined in terms of the state variables $y = (T, v, q, p)$ can be written as eqn [1], where A and P identify, respectively, the contribution to the full equation tendency of the nonparameterized and parameterized physical processes.

$$\frac{\partial y}{\partial t} = A(y, t) + P(y, t) \quad [1]$$

The time integration of eqn [1] from the initial time t_0 to the forecast time t (eqn [2]) describes the time evolution of the atmospheric flow from the initial state $y(t_0)$ to the final state. equation (2)

$$y(t) = y(t_0) + \int_{t_0}^t [A(y, \tau) + P(y, \tau)] d\tau \quad [2]$$

The initial state of the system, $y(t_0)$, is defined by observed weather variables. Denote by $\sigma\tau$ the vector of all meteorological observations made in a time interval 2Δ centered at time t_0 , $t_0 - \Delta < \tau < t_0 + \Delta$. The initial state of the system $y(t_0)$ is defined in such a way that, for all times τ with $t_0 - \Delta < \tau < t_0 + \Delta$, $y(\tau)$ is closest to $\sigma(\tau)$. Practically, $y(t_0)$ is computed by minimizing a cost function $J(y(t_0))$ (eqn [3]).

$$J(y(t_0)) = d_B(y(t_0), y_B(t_0)) + \int_{t_0-\Delta}^{t_0+\Delta} d_O(y(\tau), O(\tau)) d\tau \quad [3]$$

Figure 1 (a) 5-day forecast probability of cold 850 hPa temperatures (850 hPa temperature anomaly with respect to climatology smaller than 8°). (b) 5-day forecast probability of more than 5 mm day^{-1} of precipitation. (c) 5-day 850 hPa temperature forecast given by a single deterministic forecast. (d) Observed temperature field at 850 hPa. Contour isolines for 20%, 40%, and 80% probabilities, with shading for values greater than 20%. Contour interval is 4° for temperatures (dashed blue for negative and solid red for positive values).

The cost function is the sum of the distance $d_B(-, -)$ of $\gamma(t_0)$ from the background field $\gamma_B(t_0)$ and the time-integrated distance $d_O(-, -)$ of $\gamma(\tau)$ and the observation vector $o(\tau)$. (Note that the two distances are different, since one is defined using the covariance matrix of background errors and the other the covariance matrix of observation errors.) The minimum of the cost function can be considered as the best estimate of the true state of the atmosphere. This computational process is referred to as data assimilation. Note that the accuracy of a data assimilation procedure depends on the accuracy of approximations of the atmospheric model used to compute $\gamma(\tau)$ starting from $t_0 - \Delta$ as in eqn [4].

$$\gamma(t) = \gamma(t_0 - \Delta) + \int_{t_0 - \Delta}^t [A(\gamma, \tau) + P(\gamma, \tau)] d\tau \quad [4]$$

Moreover, in order to compare the two vectors γ and o , the atmospheric model is used to transform observed variables into atmospheric state vector variables (i.e., to go from the observations' phase-space to the model variables' phase-space).

Some of the observations, such as those from weather balloons or radiosondes, are taken at specific times at fixed locations. Others, such as those from airplanes, ships, or satellites, are not fixed in space. Generally speaking, there is a great variability in the density of the observation network, with data over oceanic regions, in particular, characterized by very coarse resolution. Observations cannot be used directly to start model integrations, but they must be modified in a dynamically consistent way to obtain a suitable data set.

Figure 2 Schematic of a two-dimensional section of the phase space Ω of the atmospheric system. The system attractor is the set of past, present, and future atmospheric states $y(t)$. The time evolution of the system between the initial time t_0 and time t_1 is represented by the dotted line connecting the points $y(t_0)$ and $y(t_1)$ (the orbit of the system between t_0 and t_1).

Sources of Forecast Errors

The facts that at any time t_0 only a limited number of observations (limited with respect to the degrees of freedom of the system) are available and that part of the globe is characterized by a poor coverage introduce uncertainties in the initial conditions. Observational errors, usually in the smallest scales, amplify and through nonlinear interactions spread to the large scales, and eventually affect the skill of the latter. The presence of uncertainties in the initial conditions is one of the sources of forecast errors.

A second source of forecast error is related to the intrinsic approximations made in the numerical models of the atmospheric system. A requirement for skillful predictions is that numerical models are able to accurately simulate at least the effects of the dominant atmospheric phenomena. The facts that the description of some physical processes is only approximate and that numerical models simulate only processes with certain spatial and temporal scales induce forecast errors. (Availability of computer resources is one of the main factors that limits the complexity and the resolution of numerical models and data assimilation procedures, since, to be useful, numerical predictions must be produced in a reasonable amount of time.)

These two sources of forecast errors cause weather forecasts to deteriorate with forecast time. A third source of forecast error that is less important in the short and medium forecast range (say up to 10 days) but that can be very important for longer forecast ranges is related to the system boundary conditions (e.g., soil moisture content, ice coverage, vegetation).

It is worth pointing out that the system's initial conditions will always be known only approximately, since each piece of data is characterized by an error that depends on the instrumental accuracy. In other words, small uncertainties related to the characteristics of the atmospheric observing system will

always characterize the initial conditions. The growth of small initial errors into large forecast errors is due to the chaotic behavior of the atmosphere, which implies that two initial states differing only slightly will depart from one another very rapidly as time progresses.

Chaotic Behavior of the Atmosphere

A dynamical system shows 'chaotic' behavior if orbits exhibit sensitive dependence to initial conditions. An orbit is characterized by sensitive dependence if most other orbits that pass close to it at some point do not remain close to it as time advances. The atmosphere exhibits this behavior.

Figure 3(a) shows a very intense storm that crossed France and Germany during 26 December 1999, and the other three panels of the figure show three 2-day forecasts started from very similar initial conditions at 1200 UTC (coordinated universal time) on 24 December 1999. The differences among the three initial conditions were comparable to estimated analysis errors. After only 2 days of numerical integration, the three forecasts evolved into very different atmospheric situations. In particular, note the different positions of the cyclone forecast over western Germany. The first forecast (**Figure 3(b)**) wrongly positioned the cyclone over Ireland; the second forecast (**Figure 3(c)**) correctly positioned the cyclone over Germany; and the third forecast (**Figure 3(d)**) moved the cyclone too quickly over the Baltic Sea. This is an example of orbits initially close together that rapidly diverge during the time evolution.

Another example of sensitivity to the initial state is shown in **Figure 4**. The figure shows the forecasts for air temperature in London given by 33 different forecasts started from very similar initial conditions for two different dates, 26 June 1995 and 26 June 1994. There are clearly different degrees of divergence among the 33 forecasts during the two cases. All forecasts stay close together up to forecast day 10 for the first case (**Figure 4(a)**), while they all diverge already at forecast day 3 in the second case (**Figure 4(b)**). The level of spread among the different forecasts can be used as a measure of the predictability of the two atmospheric states.

The Ensemble Approach to Numerical Weather Prediction

A complete description of the weather prediction problem can be stated in terms of the time evolution of an appropriate PDF in the atmosphere's phase space (**Figure 5**). The predicted PDF of possible future atmospheric states is a function greater than zero in the phase space regions where the atmospheric state can be, with maximum values identifying the most probable future states.

The problem of the prediction of the PDF can be formulated exactly through the continuity equation for probability (the Liouville equation). Unfortunately, with the current availability of computer power, the Liouville equation that describes the PDF time evolution can only be solved for simple systems characterized by a limited number of degrees of freedom. Furthermore, the initial PDF is not well known. Ensemble prediction based on a finite number of deterministic

Figure 3 (a) Mean sea-level pressure field at 1200 UTC on 26 December 1999 and (b–d) 2-day mean sea-level pressure forecasts started at 1200 UTC on 24 December 1999 given by three members of the ECMWF ensemble prediction system. Contour interval is 3 hPa, with shading for values lower than 984 hPa.

integrations is a feasible method for predicting the PDF beyond the range of linear error growth. One of the byproducts of ensemble prediction is the possibility of estimating the forecast skill of a deterministic forecast – in other words, to forecast the forecast skill.

Ensemble prediction systems should be designed to simulate all sources of forecast errors, in particular errors due to initial and model uncertainties. The relative importance of these two sources of forecast errors depends on the characteristics (e.g., spatial and temporal scales) of the phenomena under investigation. For large-scale atmospheric patterns, research studies performed with state-of-the-art numerical models have indicated that for short and medium time ranges (say, forecasts for up to 3–5 days) errors are mainly

due to initial uncertainties. Model errors due to the parameterized physical processes start to have a nonnegligible effect after forecast day 3. By contrast, for the prediction of small-scale low-pressure systems and associated precipitation fields, for example, model errors can be as important as initial uncertainties at forecast day 2 or even earlier. For forecast times longer than 10 days (monthly and seasonal prediction), other error sources should be simulated. Examples that should be taken into account include the possible influence of uncertainties in the boundary conditions (e.g., in the soil moisture content or in the ice and vegetation coverage).

At the time of writing (September 2002), global medium-range (i.e. forecasts for up to 15 days) ensemble systems are

Figure 4 Forecasts given by the ECMWF operational ensemble prediction system (33 members at the time of running) for air temperature in London started from (a) 26 June 1995 and (b) 26 June 1994. Courtesy of Thomas Petroligis, 1995, personal communication.

part of the routine operational suites at the Meteorological Center of Canada (MSC, Dorval, Canada, <http://www.msc-smc.ec.gc.ca>), at the European Centre for Medium Range Weather Forecasts (ECMWF, Reading UK, <http://www.ecmwf.int>), and at the National Centers for Environmental Prediction (NCEP, Washington DC, USA, <http://www.emc.ncep.noaa.gov>). At these three centers global ensemble systems are run daily, and probabilistic forecasts are generated and delivered to their users. Beside this operational activity, many universities and other national and regional meteorological centers have been involved in research and experimental activities in this field.

The three ensemble systems operational at MSC, ECMWF, and NCEP are all based on a finite number of numerical integrations starting from perturbed initial conditions, but they differ in the way the perturbed initial conditions are constructed. The ensemble systems operational at MSC and

ECMWF include different schemes to simulate model errors, while the NCEP system does not simulate them. Furthermore, they are different in their ensemble size, resolution, and forecast length of the numerical integration (Table 1). (It should be stressed that availability of computer power is the main factor affecting configuration parameters such as ensemble size and resolution.)

Despite their differences, schematically each member e_j (with $j = 1, \dots, N_{\text{ens}}$) of any of these operational ensembles is defined by the time integration (eqn [5]) of the perturbed model equations (eqn [6]), starting from perturbed initial conditions $e_j(t_0)$.

$$e_j(t) = e_j(t_0) + \int_{t_0}^t [A(e_j, \tau) + P_j(e_j, \tau)] d\tau \quad [5]$$

$$\frac{\partial e_j}{\partial t} = A(e_j, t) + P_j(e_j, t) \quad [6]$$

Figure 5 Schematic of ensemble prediction. The initial $PDF(0)$ represents the initial uncertainties. From the best estimate of the initial state, a single deterministic forecast (bold solid curve) is performed. This single deterministic forecast fails to predict correctly the future state (dash curve). An ensemble of perturbed forecasts (thin solid curves) starting from perturbed initial conditions designed to sample the initial uncertainties can be used to estimate the probability of future states $PDF(t)$. In this case, two perturbed forecasts almost correctly predict the future state, and the ensemble system gives a nonzero probability of the future state to reach the observed value.

Table 1 Configuration of the global ensemble systems operational at MSC, ECMWF and NCEP (at the time of writing, September 2002): ensemble size, spectra truncation (TL149 indicates spectral triangular truncation at wavenumber 149 with linear grid), equivalent grid spacing in km, number of vertical levels (note that MSC runs with a different number of vertical levels in each perturbed forecasts), pressure at the top of the model (hPa), forecast length (days), inclusions of the simulation of observation errors, initial uncertainties and model uncertainties (Yes or No)

Ensemble	Size	Resolution (spectral)	Grid (km)	Levels	Top (hPa)	Forecast length	OBS	IC	MOD
MSC	16	TL149	135	23-28-41	10	10d	Y	Y	Y
ECMWF	51	TL255	80	40	10	10d	N	Y	Y
NCEP	24	T126 ($d < 3.5$)– T62 ($3.5 < d$)	120 ($d < 3.5$)– 250 ($3.5 < d$)	28	2.7	15d	N	Y	N

Note that in eqn [6] the term that identifies the contribution to the full equation tendency of the parameterized physical processes, $P_j(y, t)$, is different for each ensemble member. This represents the fact that model errors due to parameterized physical processes are simulated in the ensemble system.

Simulation of Initial Uncertainties

The perturbed initial conditions $e_j(t_0)$ are generated to represent the initial uncertainties. This can be accomplished by following different approaches with the constraint that the number of initial perturbations is limited to a few tens. In probabilistic terms, this is equivalent to saying that the initial-time PDF can be sampled only a small number of times.

At ECMWF, the perturbed initial conditions are defined by adding to the best estimate of the initial state $e_0(t_0)$ (computed

by minimizing $J(-, -)$, see eqn. [2]), an ensemble of initial perturbations $\delta e_j(t_0)$ (eqn [7]).

$$e_j(t_0) = e_0(t_0) + \delta e_j(t_0) \quad [7]$$

The initial perturbations $\delta e_j(t_0)$ have been designed to sample the components of the initial uncertainties with maximum growth during the forecast time (i.e., for times $t > t_0$) and during the data assimilation time, (i.e., for times $t < t_0$). This choice is based on the hypothesis that the components of the initial uncertainties with the fastest growth during the system time evolution and during the data-assimilation time period have the dominant effect on the forecast accuracy. Practically, these ‘growing directions’, called singular vectors, are computed by applying complex techniques based on iterative integrations of forward and adjoint tangent versions of the nonlinear model.

At NCEP, as at ECMWF, initial perturbations are added to the best estimate of the initial state $e_0(t_0)$. But compared to ECMWF, the NCEP initial perturbations are designed to sample only the components of the initial uncertainties that grow during the data-assimilation time interval, i.e., for times $t < t_0$. As a consequence, the two sets of initial perturbations can differ substantially. For example, ECMWF initial perturbations are characterized by smaller scales and by faster growth during the first two days of forecast integration than are the NCEP perturbations.

At MSC, a different approach is followed. First, given the set of observations $o(t)$, an ensemble of perturbed observations $o_j(t)$ is generated, $O_j(t) = O(t) + \delta O_j$. Then, the ensemble of N_{ens} initial perturbations is generated by performing N_{ens} data assimilation cycles (i.e., by minimizing eqn [3] j times, each time using a different set of perturbed observations $o_j(t)$), so that each perturbed initial state $e_j(t_0)$ is the best estimate of the atmospheric state given by the set of perturbed observations $o_j(t)$. It should be mentioned that, since the MSC ensemble also simulates model errors, each data assimilation procedure is performed using a different model version (see next section).

The differences between the three methods seem subtle, but they have a significant impact on the characteristics of the ensemble systems (e.g., on the ensemble dispersion). The debate on what is the best approach is still open.

Simulation of Model Errors

As is the case for the simulation of initial uncertainties, there is not yet agreement within the scientific community about the best way to simulate model errors.

At MSC, different – and on average equally skillful – parameterization schemes are used when numerically integrating each perturbed member. The rationale of this approach is that, despite the fact that these different schemes perform equally on average, they can perform significantly differently on single occasions. Schematically, the MSC approach can be described as follows. Suppose that the following different parameterization schemes are given: three schemes that simulate moist processes (C_1 , C_2 , and C_3), three schemes that simulate turbulent diffusion processes (D_1 , D_2 , and D_3) and two radiation schemes (R_1 and R_2). Using a different combination of the schemes, an ensemble system with 18 perturbed members, each integrated with a different model, can be designed. Schematically, each member of the MSC ensemble is defined by eqn [5] with eqn [8].

$$P_j = C_{k,j} + D_{k,j} + R_{k,j} \quad [8]$$

The full tendency due to the parameterized physical processes is computed by adding the tendencies computed by different combinations of the schemes simulating moist processes, turbulent diffusion, and radiation ($C_{k,j}$ means that the j th ensemble member is integrated using the C_k).

At ECMWF, the random component of model errors due to parameterized physical processes is simulated by stochastically perturbing the tendency due to the physical processes. Schematically, each member of the ECMWF ensemble is defined by eqn [5] with eqn [9], where P is the unperturbed tendency due

to all the parameterized physical processes, and r_j is a vector of random numbers.

$$P_j(e_{j,t}) = [1 + r_j]P(e_{j,t}) \quad [9]$$

At the time of writing, in the ECMWF operational ensemble system the random numbers r_j are uniformly sampled in the interval $-0.5 < r_j < 0.5$.

Operational Applications of Ensemble Prediction

Ensemble prediction products are becoming increasingly popular. Figure 6 and Figure 7 show two examples of weather products designed, respectively, for a forecaster interested only in a single location and for a forecaster interested in a large area. Figure 6 shows the 10-day ensemble prediction of temperature, geopotential height, precipitation, and cloud cover for London given by the ECMWF ensemble prediction system started on 28 March 2000. This shows, for example, that wind speed will decrease during the first three forecast days, that temperature will rise slightly, and that there could be intense precipitation (up to 20 mm/12 h) on 2 April. The fact that the size of the box-and-whiskers increases during the forecast time, especially after 1 April, indicates that the ensemble spread increases, suggesting future less predictable situations.

The second product has been designed for a forecaster interested in assessing the accuracy of an 84 h prediction of mean sea-level pressure (MSLP) and precipitation over north-eastern Spain. Figure 7(a) shows the observed MSLP (more precisely the ECMWF analysis) and the 24 h precipitation forecast given by the ECMWF high-resolution model, which can be considered as a good approximation of the large-scale features of the actual precipitation field. This panel shows that more than 40 mm of rain affected a large area across the Spanish–French border. Figure 7(b) shows the 84 h forecast given by the ECMWF unperturbed (control) forecast. Figure 7(c) shows the 84 h MSLP forecast given by the ECMWF ensemble-mean and the ensemble standard deviation (shading). Figure 7(d) shows the 84 h probability forecast of more than 20 mm day⁻¹ of precipitation given by the ECMWF ensemble system. Figure 7(c) and (d) can be used to assess the possible accuracy of the forecast given by the control forecast (d). Figure 7(c) shows that the ensemble-mean forecast predicts an atmospheric flow (at the surface) similar to that predicted by the control forecast, and that the ensemble standard deviation, which is a measure of the agreement/disagreement among the ensemble members, is not particularly large in the area of interest (i.e., across the Spanish–French border). This can be used as an indication that the ensemble spread in the area of interest is rather small and thus that the situation should be predictable. Figure 7(d) shows that there is a probability of more than 40% that intense precipitation will affect the area of interest, again confirming that there is good agreement among the ensemble members in predicting this phenomenon.

These two figures constitute simple examples of how ensemble prediction can be used to complement single deterministic forecasts with probabilistic information to try to assess the forecast accuracy. It is worth mentioning that ensemble

Figure 6 Meteogram for London showing the ECMWF ensemble prediction forecasts for cloud cover, total precipitation, 10-m wind-speed, and 2-m temperature for London/Heathrow. The forecast started at 1200 UTC on 28 March 2000. Box-and-whiskers show the minimum and maximum values, the 25% and the 75% quartiles, and the median of the forecasts given by the 51-member ECMWF ensemble system.

products have started to be used experimentally in business applications such as ship routing and energy-demand predictions.

Validation of Ensemble Systems

The primary purpose of ensemble systems is to estimate the PDF of forecast states. As a consequence, the quantitative evaluation of ensemble systems should be based on the comparison of the forecast PDF with the observed PDF. In

particular, verification measures should be designed to assess the statistical consistency and usefulness of the predicted PDF. These two properties should be assessed by considering the first-order moment of the predicted PDF (the ensemble-mean) and the second-order moment (ensemble standard deviation). Verifications should be performed both at grid-point level (i.e., for single locations) and considering large-scale atmospheric patterns (i.e., regimes characterized by a blocked or a zonal flow over the Euro-Atlantic sector). The skill of an ensemble system should be compared with the skill of some reference

Figure 7 (a) Mean sea-level pressure (MSLP) field observed (i.e., analysis) at 0000 UTC on 10 June 2000 and verification for the 24 h accumulated precipitation (24HTP) between 1200 UTC of 9 and 10 June (this verification field, defined as the 24 h forecast from the ECMWF high-resolution model started on 9 June, can be considered a good approximation of the large-scale features of the observed precipitation field). (b) ECMWF ensemble unperturbed (i.e., control) forecast started on 6 June ($t+84$ h for MSLP and 24HTP predicted between $t+72$ h and $t+96$ h). (c) ECMWF ensemble-mean and standard deviation $t+84$ h forecasts for MSLP. (d) Corresponding ECMWF ensemble probability of more than 20 mm day⁻¹ of precipitation. Contour interval is 2.5 hPa for MSLP and 1 hPa for MSLP standard deviation. Shading for the 24HTP in (a) and (b) is for 2, 10, 20, and 40 mm day⁻¹ and shading for probability in (c) is for 5%, 10%, 20%, and 40%.

systems (benchmarks) such as climatology or simpler PDF-prediction systems.

Numerical weather forecasts are often used by decision-makers to decide whether to take an action to protect against a possible loss. Typically, the decision maker would spend an amount C if an event is predicted to protect himself against a loss L (with $L > C$). The economic value of a forecasting system can be assessed using skill measured by coupling contingency tables and cost-loss decisions. The economic value of a forecast can be defined as a function of the false alarm rate and the probability of detection of the

system. Since this measure is defined for both categorical and probabilistic forecast, it can be used to compare the economic value of a single forecast and of an ensemble forecasting system.

Figure 8 shows, for December 1999 over Europe, the average economic value of the $t + 120$ h $t + 120$ h prediction the event, '24 h accumulated precipitation greater than 10 mm day⁻¹', for three different forecasts, specifically the single deterministic forecasts given by the ECMWF unperturbed (control) forecast and by the ensemble-mean, and the probabilistic prediction generated using the whole ensemble system

Figure 8 Comparison of the economic value of the ECMWF $t+120$ h forecasts given by the unperturbed (control) forecast (blue line), the ECMWF ensemble-mean (green line), and the ECMWF ensemble probability (red line), average for December 1999 over Europe, for the event '24 h total precipitation larger than 10 mm day⁻¹'.

(the economic value varies from 0, for a forecast as skillful as climatology, to 1 for a perfect forecast).

Figure 8 shows that the economic value for the ensemble probabilistic prediction is definitely greater than the economic value of the two probabilistic predictions, especially for small cost/loss ratios. Considering the deterministic predictions, Figure 8 shows that (for the period and the event considered) the ensemble-mean and the control forecast have about the same economic value for the 5 mm day⁻¹ threshold, while for the 10 mm day⁻¹ threshold the control forecast performs better for small cost/loss ratios but worse for large values.

This result indicates that for December 1999 a decision maker interested in predicting a binary event 'rainfall greater than 5 or 10 mm day⁻¹' over Europe would have had a higher return if by taking decisions (protect/not protect) according to the ensemble forecast than from any single deterministic forecast.

Conclusions

The operational implementation of ensemble prediction systems has changed the approach to numerical weather prediction from deterministic (i.e., based on a single forecast) to probabilistic. Ensemble systems provide a possible way to estimate the probability distribution function of forecast states. They have been developed following the notion that

uncertainties in the initial conditions and in the model formulation are the main sources of forecast errors.

Ensemble prediction systems are particularly useful, if not necessary, for providing early warnings of the risk of extreme weather events. For example, ensemble systems can be used to predict probabilities of intense precipitation events. The economic value of ensemble prediction is higher than the economic value of single deterministic forecasts. Global ensemble systems can be used to provide boundary and initial conditions for higher-resolution, limited-area ensemble prediction systems.

Research activity is in progress in many different areas to further improve the accuracy of the operational ensemble prediction system, and is in hand to improve the representation of initial and model errors, and possibly to use ensemble approaches to data assimilation. Multimodel, multianalysis ensemble systems based on a set of integrations performed with different models and starting from analyses constructed using different data assimilation schemes are under investigation. Work is also under way to further develop ensemble products that can be used more easily in businesses heavily affected by weather (e.g., the shipping industry, the energy sector, safety and protection agencies).

Introduction

Chaos is difficult to quantify. The nonlinear dynamic that gives rise to chaos links forecasting on the shortest time scales of interest with behavior over the longest time scales. In addition, the statistics which quantify chaos forbid an appeal to most of the traditional simplifications employed in statistical estimation. Nevertheless, both the concept of chaos in physical systems and its technical relative in mathematics have had a significant impact on meteorological aims and methods. This is particularly true in forecasting. Chaos implies sensitivity to initial conditions: small uncertainties in the current state of the system will grow exponentially-on-average. Yet, as discussed below, neither this exponential-on-average growth nor the Lyapunov exponents that quantify it reflect macroscopic predictability. The limits chaos places on predictability are much less severe than generally imagined. Predictability is more clearly quantified through traditional statistics, like uncertainty doubling times. These statistics will vary from day to day, depending on the current state of the atmosphere. Maintaining the uncertainty in the initial state within the forecast is a central goal of ensemble forecasting (*see Data Assimilation and Predictability: Ensemble Prediction*). Achieving the ultimate goal of meaningful probability forecasts for meteorological variables would be of great societal and economic value. Fundamental limitations in the realism of models of the atmosphere will limit our ability to make probability (PDF) forecasts, just as uncertainty in the initial condition limits the utility of single forecasts even if the model is perfect.

Initially, it appears that chaotic systems will be unpredictable, and this is true in that it is not possible to make extremely accurate forecasts in the very distant future. Yet chaos *per se* does not imply one cannot sometimes make accurate forecasts well into the medium range. And perhaps just as importantly, with a perfect model one can determine which of these forecasts will be informative and which will not at the time they are made. As we shall see below, both the American and the European weather forecast centers have adopted this strategy operationally, with the aim of quantifying day-to-day variations in the likely range of future meteorological variables. Quantifying this range can be of significant value even without a perfect model. Although accurate probability forecasts are likely to require a perfect model, current operational ensemble prediction systems already provide economically valuable information on the uncertainty of numerical weather prediction (NWP) well into 'week two,' and research programs on seasonal time scales are underway.

Why is perfect foresight of the future state of the atmosphere impossible? First, it should be no surprise that if our knowledge of the present is uncertain then our knowledge of the future will also be uncertain; the question of prediction then turns to how to best quantify the dynamics of uncertainty. Here the full

implications of chaos, or more properly of nonlinearity, mix what are often operationally distinct tasks: observing strategy, data assimilation, state estimation, ensemble formation, forecast evaluation, and model improvement. This complicates the forecasting problem beyond the limits in which classical prediction theory was developed. First the traditional goal of a single best first guess (BFG) forecast with a minimal least-squares error is not a viable aim in this scenario, nor is a least squares solution desired. Indeed (as discussed below) this approach would reject the perfect model which generated the observations! Second, current models are not perfect. The term 'model inadequacy' is used to summarize imperfections in a given model and the entire model class from which that model is a member. Model improvement and the search for a superior model class, along with the investigation of more relevant measures of model skill, are areas of active research.

A Mathematical Framework for Modelling Dynamical Systems

Chaos is a phenomenon found in many nonlinear mathematical models. While one should never forget the distinction between the model and the system being modeled, precise mathematical definitions are more easily made within the perfect model scenario (PMS). Within this useful fiction, one assumes that the model in-hand is itself the physical system of interest. Before moving back to forecasts of the real world, of course, one must recover from this self-deception.

Given a model, an initial condition is simply an assignment of values to all model variables at a particular starting time. Thus the initial condition reflects the current state of the model: it is a vector $\mathbf{x}(t)$ which specifies the value of every variable in the model at time t . For the classical model of a pendulum, the state consists of two variables (the angle and the angular velocity). These two numbers completely define the current state of the model, and so the model is called two-dimensional, or, equivalently, said to have a two-dimensional state space. The famous Lorenz model of 1963 is three-dimensional, as there are three variables: $\mathbf{x} = (x, y, z)$. These low-dimensional systems should be contrasted with the state of an operational NWP model, which may consist of over 10 million variables.

The sequence of states a dynamical system passes through defines the history of the system; this sequence is called a trajectory. For deterministic systems, any single state $\mathbf{x}$ along a trajectory defines all future states of the system. For the classical pendulum, these solutions can be written down analytically; but for all but the simplest nonlinear systems only numerical solutions exist. Thus it is difficult to prove that a given realization of the Lorenz model is chaotic, and even more so modern NWP models.

Chaos

Mathematically, a chaotic system is a deterministic system in which (infinitesimally) small uncertainties in the initial condition will grow, on average, exponentially fast. The average is taken over (infinitely) long periods of time. Of course, finite uncertainties often grow rapidly as well, in which case any uncertainty in the initial condition will limit predictability in terms of a single BFG of the future state, even with a perfect model. But inasmuch as it is defined by the behaviour of (infinitesimally) small uncertainties of (infinitely) long periods of time, chaos *per se* places no limits of the growth of finite uncertainty over a finite period of time. Chaotic systems are often said to display sensitive dependence on initial condition (SDIC), a technical term for systems in which states initially very close together tend to end up very far apart, eventually.

Suppose the true state of the system is $\bar{x}$: what is the behaviour of a near-by solution $\hat{x}$ where $\hat{x} = \bar{x} + \epsilon$? In the pendulum, a small initial ϵ grows slowly, if at all. In a chaotic system, the magnitude of ϵ will grow exponentially-on-average; yet this does not imply that the actual magnitude of ϵ ever grows exponentially in time. Indeed, since ϵ is a distance and $|\epsilon| > 0$ for any given value of t , one can always define a value

$$\lambda = \frac{1}{t} \log[|\epsilon(t)|/|\epsilon(0)|]$$

for any system, chaotic or not! In this case, observing a value of $\lambda > 0$ for finite t does not even suggest exponential growth. Statistics like λ become interesting only when they approach a constant as $t \rightarrow \infty$; by definition, chaos reflects properties only in this limit.

Clearly, chaos includes special cases where magnitude of ϵ is growing uniformly, say doubling every second; but it also allows the more common case where the growth of ϵ is a function of the state x and hence changes with time. In general, the growth will not be uniform in time. In fact in some chaotic systems, including the Lorenz 1963 model, there are regions of the state space in which every ϵ will decrease! Such regions are said to represent ‘return of skill’ as forecasts become more accurate in the least-squares sense as time passes.

For instance, consider the case where, on average, half the time ϵ is constant and the other half of the time it grows by a factor of four. This will yield in the same exponential-on-average growth as doubling every time step, yet there will be times when prediction is easy. Or for a more extreme case, consider where ϵ shrinks by a factor of two 9 times out of 10, but once in 10 grows by a factor of 2^{19} (about half a million); again this is exponential-on-average growth equivalent to doubling every time step. The question, then, is whether or not these variations of predictability can be identified in advance. As discussed below, ensemble forecasts aim to do just that.

The Statistics of Chaos: Lyapunov Exponents and Doubling Times

Given a deterministic system which remains in a bounded region of state space, chaos is defined by a statistic called the Lyapunov exponent. In a one-dimensional system, the Lyapunov exponent reflects the logarithm of the (geometric) average

growth of infinitesimal uncertainties. In the limits $\epsilon \rightarrow 0$ and $t \rightarrow \infty$, the geometric average of $|\epsilon(t+1)|/|\epsilon(t)|$ defines the Lyapunov exponent, usually called λ . Note that nowhere is there the suggestion that $|\epsilon(t)| \approx |\epsilon(0)|e^{\lambda t}$. A system will have as many Lyapunov exponents as the dimension of the state space. The largest Lyapunov exponent is often called the ‘leading’ Lyapunov exponent, and if the leading Lyapunov exponent of a bounded deterministic system is positive, then the system is ‘chaotic.’ Hence the three systems noted above – one in which ϵ doubles every time step, and the other two in which ϵ sometimes grows and sometimes does not – each have the same Lyapunov exponent. Typically, the logarithm is taken with base two, so that if, for example, the uncertainty doubles every second, the Lyapunov exponent is one bit per second, thus the Lyapunov exponent is an average rate.

Also note that for every state x on the attractor, there corresponds a unique direction in state space associated with the leading Lyapunov exponent. If the state space has a dimension greater than one, then estimating Lyapunov exponents involves matrix multiplication along a trajectory. Matrix multiplication does not commute, thus when dealing with statistics like Lyapunov exponents one has to apply multiplicative ergodic theorems; this makes many of their properties appear counterintuitive. Many intuitive methods of statistical estimation fail when applied to chaotic systems. None of this is surprising, since most statistical intuition is developed in the context of more familiar ergodic theorems.

If the sum of all the Lyapunov exponents is negative, then the trajectories will evolve towards a set whose dimension is less than the dimension of the state space; this set is called an ‘attractor.’ An attractor may be something as common as a fixed point, a periodic orbit, or a torus; in such cases the attractor has simple geometry. Alternatively, an attractor may have a strange geometry: it may consist of a fractal set of points in state space, in which case it is called a ‘strange attractor.’ Note that being chaotic reflects a property of the dynamics of the system, while strangeness reflects the geometry of the set on which the system evolves, not the dynamics of the evolution itself. Given a chaotic system with a strange attractor, the choice of initial conditions should reflect the local structure of the attractor, yet this structure is determined by the long-time behavior for the system. In this way, chaos links the longest time scales of the system to the shortest time scales of interest.

The attractor of the Lorenz 1963 model with typical parameter values is shown in [Figure 1](#). It is believed that there are parameter values for which the Lorenz 1963 model has chaotic dynamics on a strange attractor, but, as noted above, such properties are difficult to prove even in this fairly simple system of equations.

In meteorology, the doubling time, τ_2 , provides a more traditional measure of predictability than the Lyapunov exponents. It is also a more relevant measure, although if the growth is not uniform then the time required for an initial uncertainty at x to increase by a factor of four will not be twice the doubling time at x (or, more generally, $\tau_{q^2} \neq 2\tau_q$). In practice, one just has to look at the statistics. An average time is a more relevant measure of predictability than an average rate. Computing an average rate requires stating the duration over which to average *a priori*, while the relevant time scale is itself the quantity of interest. In fact, one can generate a family of chaotic systems

Figure 1 The distribution of uncertainty doubling times on the Lorenz attractor. Points colored red double in less than one Lorenz second. Points colored red have a $\tau_2 \leq 1$ Lorenz time step, orange points $\tau_2 \leq 2$, and so on through yellow, light green, dark green, blue, and purple. The mauve points on the inner and outer edges of the attractor for which $\tau_2 \leq 7$. The density of points with $\tau_2 \leq 5$ has been reduced for clarity. The visible line in the foreground which separates red points from each of the other colors shows the location of points which double just as they enter the region in which all uncertainties decrease, referred to in the text. Adapted with permission from **Figure 1** of Smith LA (1994) Local optimal prediction. *Philosophical Transactions of the Royal Society of London Series A* **348**: 371–381.

each of which has a leading Lyapunov exponent greater than one, yet containing members with an average τ_2 as large as desired! Indeed, estimating a time-like statistic with the inverse of an average rate is a dubious endeavor. To convince yourself of this, consider estimating the average value of a by one over the average of $1/a$, when a is uniformly distributed between zero and one.

In **Figure 1**, points on the Lorenz attractor are colored by the doubling time of an infinitesimal uncertainty aligned initially in the local orientation corresponding to the leading Lyapunov exponent. The coloration is neither uniform nor random. Note the line separating the red points on one side from the band of each color on the other. The origin of this demarcation will be explained in the next section. Red points have a τ_2 of less than one second, for orange points it is less than two, and so on through yellow, light green, dark green, blue, and purple. The mauve points on the inner and outer edges of the attractor for which $\tau_2 > 7$. This is a clear illustration that predictability will vary with initial condition in an organized way! Which, in turn, suggests that predictability will vary in a predictable way: quantifying this in practice is the goal of ensemble forecasting. Yet even within the PMS, one is interested in finite initial uncertainties and forecasts over a finite duration. The accuracy of such forecasts need not reflect the Lyapunov exponents of the system in any way. Thus chaos *per se* places few restrictions on predictability.

True Limits of Predictability

So what are the limits to predictability of a chaotic system? The answer depends on the use to which the forecast is to be put.

Linear prediction theory aims to identify the optimal least-squares predictor: the model which, on average, yields a BFG future state with the smallest (squared) prediction error. This is a coherent approach to Gaussian uncertainties evolved under linear models, but not when applied to nonlinear systems with uncertain initial conditions.

If the initial condition is uncertain, then this uncertainty will evolve nonlinearly. It can be proven that given a series of uncertain observations of a chaotic system, there will always be uncertainty in the current state. This is the case even if a perfect model is in hand and the observations extend into the infinite past. Even then, there will be a set of indistinguishable states, each consistent with the series of observations and with the long-time dynamics of the system. The ideal forecast is then an ensemble forecast, where the members of the ensemble are drawn from the set of indistinguishable states, and each member weighted with its likelihood given the available observations. In the limit of infinitely large ensembles, this forecast can accurately quantify the relative probability of different events and the decay of predictability, correctly reflect the variations in each from day to day.

In practice, ensemble forecasting is a Monte Carlo approach to estimating the probability density function (PDF) of future model states given uncertain initial conditions. An ensemble forecast for the Lorenz 1963 system is shown in **Figure 2**. The vertical axis is time, the horizontal axis is the variable x from the Lorenz system, and each line at constant time represents the probability density function of x at that time.

At $t = 0$ the system is near $x \approx 0$ and the initial ensemble consists of 512 initial states, each of which is both indistinguishable from the true state given the observations and also consistent with the long-term dynamics of the system (that is, 'on the attractor'). This constitutes a perfect ensemble. While only the value of the x component is shown, each member of the ensemble is a complete state of the system, and corresponding figures could be drawn for y and z .

Initially the distribution spreads out as might be expected, while the average value of x increases. At $t \approx 0.4$, however, the volume of the convex hull of the ensemble shrinks, showing a true 'return of skill' as the ensemble enters a region where all uncertainties decrease! Here a BFG forecast at $t \approx 0.4$ is expected to be more accurate than the corresponding forecast at $t \approx 0.2$. This is the origin of the discontinuity in doubling times noted above in **Figure 1**: red points to one side of the line double just before entering the region, while points in the rainbow bands just across the line enter the shrinking region before they double, and must wait a finite time to be advected out of the shrinking region before they might double. Hence the discontinuity.

Returning to **Figure 2**, notice that as distribution returns near $x = 0$ at $t \sim 0.7$, a small fraction of the ensemble members switch to the wing of the attractor with negative values of x , while the majority make another circuit with $x > 0$. Owing to the symmetry of the attractor, there is a somewhat artificial return of skill at $t \sim 1.5$. After this, however, the ensemble members divide more evenly between the two wings of the

Figure 2 Evolution of a perfect ensemble under a perfect model, showing the probability distribution of one component of the model state, the variable x , in the Lorenz system. Time is denoted along the ordinate, while the abscissa is centered about zero. Each line reflects a particular time: the height reflects the probability density at that value of x , while the color of each line reflects the standard deviation of the ensemble at that time. Adapted with permission from Figure 23 of Smith LA (1997) The maintenance of uncertainty. Proceedings of the International School of Physics “Enrico Fermi”, course CXXXIII, pp. 177–246, Società Italiana di Fisica, Bologna, Italy.

attractor, and the distribution turns blue. The color here reflects the standard deviation of the forecast ensemble.

At this point, the standard deviation of the forecast is greater than that of a set of points taken at random from the attractor (that is, the *climatology*). Many classical measures of predictability would not see the significant information content that the forecast obviously continues to possess; good skill scores should reflect the information content of the ensemble. Even more worrying, the ‘optimal’ least-squares forecast at $t = 2.7$ would be near $x = 0$ where there is zero probability of observing the system. One important point illustrated here is that knowing the mean value exactly is often of much less value than knowing the likely distribution of values even approximately. A second point is that tuning nonlinear models with the aim of a ‘better’ average least-squares error will make the models worse, as it systematically forces model parameters away from more realistic, but heavily penalized, behavior. Such models are expected to be underactive rather than realistic.

The information in the initial ensemble will slowly diffuse away, and whether or not the information in the forecast at any

given time is useful depends on the aims of the user. Eventually, any finite ensemble will itself become indistinguishable from a random draw from the climatology. At this point the forecast is useless, but this time is unrelated to the Lyapunov exponent, or the doubling time, or any other measure of infinitesimal uncertainties.

Accountable Ensemble Forecasts

Corresponding to each probability forecast there is only a single verification; thus no single forecast can be evaluated. Rather, the quality of a (long) series of probability forecasts must be considered. And inasmuch as nonlinearity will mix aspects of data assimilation (see **Data Assimilation and Predictability: Data Assimilation**), ensemble formation and model inadequacy, the ensemble prediction system (EPS) can be evaluated only as a whole. This should not come as a surprise, since in a nonlinear system one expects to lose the benefits of linear superposition.

While the absolute accuracy of the EPS will vary with the level of initial uncertainty, ensemble forecasts under a perfect model using perfect initial ensembles are ‘accountable’: the uncertainty in any forecast variable computed from this ensemble will reflect the true value with an accuracy limited only by the finite number of members in the ensemble. Karl Popper introduced the notion of accountability for BFG forecasts in order to illustrate that a good model should indicate how accurately the initial condition must be measured in order to guarantee the accuracy of a forecast at any fixed lead time. The notion is easily extended to ensemble forecasts, in that an accountable ensemble forecast system should indicate how large an initial ensemble should be in order to reflect events accurately with a given level of probability.

Of course, the detailed shape of each forecast distribution will differ from day to day, **Figure 2** shows the probability distribution for a particular initial condition and set of observations. Yet if the EPS is accountable, then as the number of members in the ensemble is increased, the probability forecast will grow more accurate in a predictable way. For example, every time the ensemble size is doubled, the frequency with which any particular variable in the verification will fall outside the ensemble will be cut in half. [In fact, the ensemble size must be increased from N members to $(2N + 1)$ members, since the probability that the next random draw falls outside the current range is $2/(N + 1)$.]

In practice, ensembles are not drawn from a set of indistinguishable states; there are a number of competing methods now used operationally, and other methods are soon to join them. Current formation schemes include sampling directions of forecast errors of the recent past, or the directions of fastest growth in the near future. Neither approach attempts to sample the initial uncertainty accurately, and thus accurate probability forecasts could not be expected from the raw forecasts, even were the models to be perfect.

Operational ensembles typically consist of between 10 and 100 members, evolved over a duration of two weeks, although seasonal ensembles are a current topic of research. Recalling that operational model-state spaces typically have ten million dimensions gives an indication of just how difficult sampling

the initial uncertainty may prove to be. Despite the technical difficulties, the value of operational ensembles is reflected in [Figure 3](#), a 42-hour forecast for 26 December 1999. The three panels in the top left corner show the low-resolution (control) and high-resolution (T319) BFG forecasts, and the more colourful analysis (1 0 5) which serves as the verification. The color in the analysis reflects the intense winter storm that swept across Europe. The other 50 panels in the figure each show a member of the ensemble forecast at $t = +42$ hours. This collection of ‘postage stamp’ maps is analogous to a single PDF at constant time in [Figure 2](#). Note that about 20% of the ensemble members contain storms, and that even though there is no known way to extract an accountable probability estimate from this operational forecast, there is significantly more information than is provided by the control forecasts. In its present state, this information is already of significant societal and economic value.

Physical Systems and Mathematical Models

Arguably that, no physical system is ever isolated, and perturbations from outside the system imply that no dynamical system can be perfectly modeled as deterministic. What then does one mean by saying that a physical system is chaotic? Lorenz (1993) suggests a physical system should be called chaotic if its behavior would be chaotic were it to be isolated. This, of course, assumes there is perfect mathematical description of the hypothetical isolated system, but it is similar to the manner in which other mathematical terms are interpreted in physics; for example, the definition of periodicity in a physical system. Periodicity is a useful concept in physics, although arguably no physical system is truly periodic. Similarly, chaos may be a useful concept within physics, even if no physical system is truly deterministic.

One property that distinguishes periodic and chaotic systems is that periodic systems eventually return to exactly the same state x in state space. While this never happens in chaotic systems, near returns do occur for all points on the attractor; the longer is the duration of the observations, the closer are the nearest returns. Such systems, like the Lorenz 1963 model, are said to be ‘recurrent.’ What does it mean to say a physical system is recurrent.

At this point one has to leave the perfect-model scenario behind. Observations of a physical system are at best uncertain measurements of variables in the system’s state space (if such a thing exists); in order to use them in the model the observations must be cast into a model-state space. Mathematically, a data assimilation scheme (see [Data Assimilation and Predictability: Data Assimilation](#)) is simply a projection operator which accomplishes this task. Whatever the projection operator may be, the fact that forecasts are made in the model-state space holds deep consequences for attempts to make accountable probability forecasts. Estimates of predictability reflect the limitations of our models, while the underlying physical system is not so constrained.

Once some method of data assimilation is adopted so that the observations of the system can be projected into the model-state space, one can ask if a physical system is likely to be recurrent within a particular model-state space. Will two

similar states be observed during the likely duration of the observations? Over the lifetime of the system? Often the answer is yes.

Many physical systems are also recurrent within the model-state space over the time of a typical experiment. Near recurrence in the model-state space opens up many modeling possibilities, the simplest being to use (local) linear regression (see [Statistical Methods: Data Analysis: Time Series Analysis](#)). It also introduces the possibility that we can learn from past mistakes, improving the model by identifying state-dependent systematic errors. Of course, doing so may increase the dimension of the model-state space to the extent that given the available observations it is no longer recurrent!

Given that the estimated recurrence time of the Earth’s atmosphere is longer than the lifetime of the Solar System (longer, in fact, than the expected lifetime of the Universe!), this remedy is not available to meteorologists modeling the global circulation. Of course, one may be able to exploit recurrence in building parameterizations (see [Boundary Layer \(Atmospheric\) and Air Pollution: Modeling and Parameterization](#)) or in applications on smaller scales over shorter forecast horizons. But chaos is defined for the system (or model) as a whole. There is a clear and useful intuition of what is meant by the concept of ‘approximately periodic,’ which is lacking for the phrase ‘approximately chaotic.’ Further, it is not obvious how to interpret physical systems as chaotic, if they are not expected to exist over the time scales required for chaos to manifest itself in their mathematical analogs.

Loss of Predictability: Model Inadequacy and Shadowing

In addition to uncertainty in the initial condition and uncertainty in parameter values, meteorologists must contend with ‘model inadequacy’: there are aspects of the real physical system that our model is simply unable to mimic. When no model in the available class of models is structurally adequate to duplicate the observed phenomena, it is unclear what is meant by the ‘correct’ initial condition or the ‘true’ parameter values. While the Bayesian agenda provides a principled scheme for handling uncertainty in initial condition and parameter value, no systematic approach is available for handling model inadequacy. Progress here requires having a good idea.

Recall that in the discussion of ‘uncertainty’ in the initial condition above, it was assumed that in addition to a best-guess initial condition, $\hat{x}$, there was also a true initial condition, $\tilde{x}$. The error in the initial condition was defined as the difference between these two points. When the model is imperfect, there is no ‘true’ initial condition (even if the model variables have the same names as the system variables) and the very concept of ‘uncertainty in the initial condition’ has to be reconsidered.

As an example, note that since the current resolution of NWP models is at best tens of kilometers, many different states of the atmosphere (with different futures) will be mapped onto the same state of the model. This is but one example of the projection effects noted above: the model initial conditions are, at best, projections of the true system state into the model-state space. The model cannot, then, be expected to reproduce the evolution of every atmospheric state, simply because there are

Figure 3 Ensemble forecast for the French storm of 1999. Each 'postage stamp' is a weather map of southern England and France. The three panels in the top left corner show two best-guess forecasts made at different model resolutions and the analysis, which indicates that the verification was rather different from either of these forecasts. Each of the 50 members of the ensemble at the time of the verification is also shown. Reproduced with permission of the European Centre for Medium-Range Weather Forecasts.

more atmospheric states than model states! Of course, the model may have trajectories which shadow the observed atmospheric states, remaining indistinguishable from the trajectory of the atmosphere given the observational uncertainty. How might meteorologists distinguish forecast failures due to limitations in the ensemble formation scheme from those due to model inadequacy? One approach is to look for 'shadowing trajectories' within the historical observations.

Given an imperfect model, there may or may not be a model trajectory that stays close to the series of observed states, no matter which data assimilation method is used to translate the observations into model states. In this context, 'close' must be interpreted in relation to the uncertainty in the observations. A model trajectory that remains near a set of target states is said to 'shadow' the target states. Each analysis will have an associated shadowing time, just as it has an associated value of τ_2 . The distribution of shadowing times reflects the relevance of model inadequacy.

If shadowing trajectories exist, then initial condition(s) which shadow may be cast in the role of 'truth' (that is, the role of $\tilde{x}$) when computing uncertainty in the initial condition, at least for forecasts that are short relative to the duration over which the model can shadow. This suggests that our very definition of 'observational noise' will itself depend on the quality of the model in hand. Indeed, many data assimilation schemes are based on the assumption that long shadowing trajectories exist almost everywhere in state space.

If no shadowing trajectory exists on the time scale of interest, then the model mixes 'uncertainty in the initial condition' and 'model inadequacy' to the extent that the former cannot be unambiguously defined. On these time scales, all model trajectories differ significantly from the observations: the set of indistinguishable states is empty, and there is no optimal method of ensemble formation. Indeed, outside PMS the issue of model improvement is linked to that of forecast usage; there need be no unique best way forward. Nevertheless, current ensemble forecasts are of great value in identifying when the forecasts are sensitive to uncertainties in the initial condition, since any single BFG forecast can be identified, at the time it is issued, as unlikely to be an accurate anticipation of reality. Hence they can be expected to provide useful identification of when the forecast will be unreliable; empirical studies suggest they are also useful in identifying forecasts which are likely to have high skill. In addition, when two members of the same ensemble lead to radically different forecasts in the medium range, determining what distinguishes them at short lead times can suggest valuable observations for improving the forecast.

In addition to ensembles over initial conditions, research is underway aimed at determining how to better include stochastic effects into nonlinear models. Such stochastic effects are commonly referred to as 'dynamical noise' to distinguish

them from observational noise; the latter alters the observations but not the trajectory. A major difficulty here is formulating a relevant state-dependent dynamical noise, as the traditional approaches tend to spread the forecast into unphysical directions. Using multiple models provides one approach, stochastic parameterizations is another.

Current research is also exploring the use of ensembles over distinct models, or even ensembles over trajectories each of which uses a variety of distinct models. Ideally, these models should be independent, so that they share as few common inadequacies as possible. Methods for allocating resources among models, and for the evaluation of the distributions so obtained as forecasts, provide yet other interesting areas of current research. The traditional goal of identifying the 'optimal' least-squares predictor need no longer be a desirable end for any real forecast user. Modern forecast users, in particular industrial users, are quite capable of exploiting probability forecasts.

Since the introduction of the electronic computer, indeed since L. F. Richardson's computations early in the last century, weather prediction has been at the forefront of research into the predictability of nonlinear dynamical systems. One safe forecast is that it will remain there for the foreseeable future.

Introduction

Dynamic meteorology is the branch of fluid dynamics concerned with the meteorologically significant motions of the atmosphere. It forms the primary scientific basis for weather and climate prediction, and thus plays a primary role in the atmospheric sciences. Most of the meteorologically important motions studied in dynamic meteorology are profoundly influenced by the facts that the Earth is

a rapidly rotating planet, and that the atmosphere on average has stable density stratification. These facts make the fluid dynamics of the atmosphere very different from traditional engineering fluid dynamics. Planetary rotation places strong constraints on large-scale horizontal motions; stable stratification places strong constraints on vertical motions. These constraints can be understood by considering the fundamental physical laws governing motions of the atmosphere.

The motions of the atmosphere are governed by the laws for conservation of mass, conservation of momentum, and conservation of thermodynamic energy. Application of these laws to motions with horizontal scales of several hundred kilometers or greater leads to simple relations among the horizontal wind, pressure, and temperature distributions. These relations form a set of diagnostic relations essential for understanding the motions that generate weather disturbances. Such motions are generally rotational in character. They can be characterized by a conservable property known as the potential vorticity, which is the fluid dynamical analogue of spin angular momentum in solid mechanics.

The latitudinal gradient of potential vorticity provides the mechanism for generation of global-scale planetary waves, which are primary features of the climate system. Superposed on these global waves are transient cyclones and anticyclones, whose energy is derived primarily from the potential energy associated with the mean Pole-to-Equator temperature gradient. Study of the development and evolution of transient weather disturbances, and of dynamical mechanisms for producing intraseasonal and interannual climate variations, are among the principal areas of study in dynamic meteorology.

The Static Atmosphere

The vertical distribution of pressure, density and temperature is determined by the hydrostatic approximation and the ideal gas law. The hydrostatic approximation, which is derived from the vertical component of the momentum equation (Newton's second law of motion), expresses the balance between the vertical component of the pressure gradient force and the force of gravity. The ideal gas law, or equation of state, expresses the relationship between pressure, density, and temperature in an ideal gas. These two equations may be combined to form the hypsometric equation, which determines the thickness of the layer of temperature T confined between the two pressure surfaces p_2 and p_1 :

$$\Phi_2 - \Phi_1 = g(Z_2 - Z_1) = R \int_{p_2}^{p_1} T \, d \ln p \quad [1]$$

where Φ is the geopotential, Z is geopotential height, T is the absolute temperature, R ($= 287 \text{ J kg}^{-1} \text{ K}^{-1}$) is the gas constant for dry air, and g ($= 9.81 \text{ m s}^{-2}$) is the acceleration due to gravity. The hypsometric equation shows that atmospheric pressure decreases more rapidly in cold air than in warm air. Thus the average altitude of a given upper-level pressure surface (e.g., the 500 hPa surface) decreases towards higher latitudes owing to the decrease of mean temperature with latitude.

Hydrostatic balance requires that pressure decrease monotonically with height in the atmosphere. Pressure may thus be substituted for height as a vertical coordinate; this has the advantages of eliminating explicit reference to the density field in the equations of motion; but it has the disadvantage that pressure varies exponentially with altitude so that equal altitude increments correspond to rapidly decreasing pressure increments as height increases. For this reason, in dynamical meteorology it is often useful to use

log-pressure coordinates in which the independent vertical coordinate z is defined by

$$z = -H \ln (p/p_0) \quad [2]$$

where $H = RT_0/g$ is an atmospheric scale-height, $p_0 = 10^3 \text{ hPa}$ (1000 mbar), and T_0 is a mean temperature. Comparing with eqn [1], it is clear that the log-pressure coordinate corresponds to actual height for an isothermal atmosphere at temperature T_0 . Under most conditions the departure of z from actual altitude is small enough to be neglected.

In the absence of precipitation, changes in temperature following the motion of individual parcels of air are controlled primarily by adiabatic expansion and compression as the air parcels move to lower or higher pressure. The thermodynamic state of such parcels can be characterized by the potential temperature, θ . Potential temperature is the temperature that a parcel of dry air initially at a pressure p and temperature T would acquire if it were moved adiabatically to the reference pressure p_0 . It is defined by the following relation, which can be obtained from the first law of thermodynamics:

$$\theta = T(p_0/p)^{R/c_p} \quad [3]$$

where c_p ($= 1004 \text{ J kg}^{-1} \text{ K}^{-1}$) is the specific heat capacity of dry air at constant pressure. Normally, surfaces of constant potential temperature in the atmosphere are quasi-horizontal with potential temperature increasing with altitude. Air parcels displaced vertically conserving potential temperature are then colder and denser than their surroundings for an upward displacement, and vice versa for a downward displacement. The atmosphere is then said to be statically stable. When diabatic heat sources (such as latent heating and radiation) are neglected, θ remains constant in time for each air parcel; thus potential temperature is conserved following the motion. Air parcels are then constrained to remain on surfaces of constant θ , which are referred to as isentropic surfaces. In a statically stable atmosphere, potential temperature can be used as the independent vertical coordinate. This isentropic coordinate system is useful for analysis of adiabatic motions, since the prediction of atmospheric motions for such conditions is reduced from a three-dimensional problem to a two dimensional problem on each isentropic coordinate surface. Because diabatic temperature changes associated with large-scale weather disturbances in the extratropics are often much smaller than adiabatic changes, isentropic analysis has proved valuable for the study of air motions associated with such disturbances.

The Equations of Motion

It is convenient to express the basic equations of dynamic meteorology in a coordinate system rotating with the Earth, and with the log-pressure altitude defined by eqn [2] as the independent vertical coordinate. The approximate conservation equations for horizontal momentum, mass, and thermodynamic energy are then as follows:

$$\frac{D\mathbf{V}}{Dt} = -f\mathbf{k} \times \mathbf{V} - \nabla\Phi + \mathbf{F}\mathbf{r} \quad [4]$$

$$\nabla \cdot \mathbf{V} + \frac{1}{\rho_0} \frac{\partial}{\partial z} (\rho_0 w) = 0 \quad [5]$$

$$\frac{DT}{Dt} + \frac{wN^2H}{R} = \frac{J}{c_p} \quad [6]$$

Here, t is time, $\mathbf{V}$ is the horizontal velocity, ∇ is the horizontal gradient evaluated at constant log-pressure, Φ is the geopotential, $w \equiv Dz/Dt$, is the vertical velocity, $f = 2\Omega \sin \phi$ is the Coriolis parameter (where $\Omega = 7.292 \times 10^{-5} \text{ s}^{-1}$ is the angular velocity of rotation of the Earth and ϕ is latitude), $\mathbf{k}$ is the vertical unit vector, Fr is the drag due to small-scale turbulent fluctuations, $\rho_0 \equiv \rho_s \exp(-z/H)$ is the basic state density (where ρ_s is density at the surface, H is the scale height defined below eqn [2], J is the diabatic heating rate, and N is the buoyancy frequency whose square is defined in terms of the height dependence of potential temperature as $N^2 = g(\partial \ln \theta / \partial z)$.

In eqns [4] and [6], D/Dt is the rate of change following the horizontal motion of a fluid parcel. This can be related to the rate of change at a given point in space by the expression:

$$\frac{D}{Dt} \equiv \left(\frac{\partial}{\partial t} + \mathbf{V} \cdot \nabla \right) \quad [7]$$

The momentum eqn [4] states that a change in the horizontal velocity following the motion of an air parcel is caused by the net imbalance among three forces: the Coriolis force caused by the rotation of the Earth, the horizontal pressure gradient force (given by the gradient of geopotential on a constant pressure surface) and the force due to turbulent dissipation (important mainly near the surface of the Earth). The equation of mass continuity [5] states that the divergence of the horizontal velocity, which tends to increase or decrease the horizontal cross-section of a fluid parcel, must be balanced by vertical motion, which increases or decreases the depth of the parcel. The thermodynamic energy eqn [6] states that the rate of change of temperature following the horizontal motion is due to the sum of the adiabatic expansion or compression due to vertical motion, plus the net diabatic heating by sources such as latent heat release and solar or thermal radiative heating.

Balanced Flow

When diabatic heating and turbulent dissipation are sufficiently small, eqns [4]–[6], together with the differential form of the hypsometric eqn [1] and suitable initial and boundary conditions, form a closed set for prediction of the meteorological fields $\mathbf{V}$, w , Φ , and T . Solutions of this complicated set of nonlinear partial differential equations can usually only be obtained by numerical methods. There are, however, certain approximate solutions that provide useful information on the relations among these field variables for large-scale atmospheric flows in the extratropical regions.

When turbulent dissipation is small, which is generally true above the lowest kilometer of the atmosphere, large-scale extratropical motions are approximately in geostrophic balance, that is, the horizontal pressure gradient force and the Coriolis force are nearly equal and opposite. The wind velocity for which this balance is exact is referred to as the geostrophic

Figure 1 Horizontal plan view of balance of forces for the geostrophic wind. $\mathbf{V}_g$, $\mathbf{P}$ designates the pressure gradient force, $\mathbf{Co}$ designates the Coriolis forces, and Φ and $\Phi - \delta\Phi$ are contours of constant geopotential on an isobaric surface.

wind, $\mathbf{V}_g$. It is derived from eqn [4] with the acceleration and turbulent dissipation terms neglected:

$$f\mathbf{V}_g = \mathbf{k} \times \nabla \Phi \quad [8]$$

This states that the geostrophic wind is parallel to lines of constant geopotential (or constant height) on a pressure surface, with speed proportional to the magnitude of the geopotential gradient on the pressure surface. As illustrated in Figure 1, the Coriolis force acts perpendicular to the wind direction (to the right of the wind in the Northern Hemisphere), while the pressure gradient force is directed opposite to the Coriolis force. Thus, the geostrophic circulation about the center of a low-pressure system in the Northern Hemisphere will be a counterclockwise circulation.

Equation [8] may be combined with eqn [1] to give the thermal wind relation:

$$f[\mathbf{V}_g(p_2) - \mathbf{V}_g(p_1)] = R \int_{p_2}^{p_1} (\mathbf{k} \times \nabla T) d \ln p \quad [9]$$

This relation, which is a consequence of geostrophic and hydrostatic balance, states that the vector difference in the geostrophic wind velocity between two pressure surfaces is proportional to the horizontal gradient of the mean temperature in the layer between the two surfaces. Since large-scale extratropical motions are in hydrostatic balance and are nearly geostrophic, eqn [9] shows that the wind and temperature fields are closely coupled. Because temperature in the extratropical lower atmosphere generally decreases with latitude, the thermal wind relation indicates that the eastward-directed geostrophic wind increases with altitude and that the strongest upper-level winds will occur where that latitudinal temperature gradient is the strongest.

Planetary Boundary Layer

In the lowest kilometer of the atmosphere, momentum transfer by small-scale turbulent eddies becomes an important component in the momentum balance so that the geostrophic approximation is no longer valid. The structure of this boundary

Figure 2 Horizontal plan view of balance of forces in a well-mixed planetary boundary layer. **V** is velocity, **P** designates the pressure gradient force, **Co** designates the Coriolis force, **Fr** designates the turbulent drag force, p is pressure, and δp is a constant pressure interval. layer depends strongly on the vertical stratification in the layer. In regions of strong vertical stability (where potential temperature increases rapidly with height) turbulence is generally weak, except in the lowest few meters above the surface where strong vertical shear of the wind provides a mechanical source for turbulent eddies. Under conditions of strong surface heating, on the other hand, the boundary layer may be convectively unstable (potential temperature decreasing with height) and strong turbulent eddies may extend throughout the lowest kilometer of the atmosphere. Over vast areas of the Earth's surface, however, the boundary layer is often near neutral static stability (potential temperature constant with height). Although accurate representation of the force exerted by turbulent eddies in eqn [4] is a challenging fluid dynamical problem, it is useful as a first approximation to simply assume that turbulent eddies exert a drag on the winds so that $\mathbf{Fr} = -k\mathbf{V}$, where k is a rate coefficient typically taken to be about 10^{-5} s^{-1} .

The force balance in the boundary layer is then a three-way balance among the Coriolis force, the pressure gradient force, and the turbulent drag force. This balance is illustrated schematically in Figure 2. Since the Coriolis force always acts perpendicularly to the wind and the turbulent drag acts in the opposite direction to the wind, a force balance can be achieved only if the wind has a component directed across the isobars towards lower pressure. The component produces net boundary layer inflow into surface low pressure systems, which by transporting mass towards the pressure minimum acts to 'spin down' the circulation.

Vorticity and Potential Vorticity

Because extratropical flow above the boundary layer is approximately in geostrophic balance, and thus tends to be parallel to height contours on pressure surfaces, the flow is characterized by cyclonic and anticyclonic gyres associated with height (or pressure) minima and maxima, respectively. Thus, the large-scale flow is dominated by a rotational flow component, which is conveniently described in terms of the vorticity (defined as the curl of the velocity vector). Although momentum is not conserved for such flows, but is changed in proportion to the small difference between the Coriolis force and the pressure gradient force, there is a dynamical quantity

Figure 3 Cylindrical column of air in adiabatic motion from a region of high static stability to a region of low static stability. The column is confined between two potential temperature surfaces, θ and $\theta + \delta\theta$, which are separated by an altitude increment δz . Adapted from Holton, J.R., 1992. *Introduction to Dynamic Meteorology*. Academic Press, New York.

that is conserved following the motion for adiabatic frictionless flows. This quantity, which is referred to as potential vorticity, is a fluid dynamical analogue of spin angular momentum in solid body dynamics. In its simplest form, potential vorticity relates the vertical component of vorticity (or spin) of a fluid column confined between two potential temperature surfaces to the depth of the column (Figure 3).

Potential vorticity can be expressed mathematically as

$$P = (\zeta + f) \frac{1}{\rho_0} \frac{\partial \theta}{\partial z} \quad [10]$$

Here, $\zeta = \mathbf{k} \cdot (\nabla \times \mathbf{V})$ is the vertical component of the relative vorticity due to the horizontal winds and f is again the Coriolis parameter, which is the vertical component of the vorticity owing to the rotation of the Earth. The sum of the local vertical components of the relative vorticity and the Earth's vorticity, $\zeta + f$, is referred to as the absolute vorticity. Equation [10] states that for a column of fluid confined between two potential temperature surfaces separated by a fixed increment of potential temperature $\delta\theta$, the ratio of absolute vorticity to the depth of the column δz remains constant. Thus, for example, a column moving from a region of high static stability (small δz) to a region of low static stability (large δz) will stretch vertically, shrink horizontally and spin faster. Because potential vorticity is conserved following the motion for adiabatic frictionless flow, the evolution of the field of potential vorticity on isentropic surfaces can easily be predicted. The potential vorticity distribution, together with suitable boundary conditions, can in turn be used to deduce the three-dimensional distribution of wind and temperature.

Zonally Symmetric Circulations

In the troposphere, temperature normally decreases from Equator to Pole owing to the latitudinal gradient in solar heating. This heating gradient induces an ageostrophic overturning circulation of air parcels in the meridional (height–latitude) plane. The overturning consists of rising motion in association with convective disturbances in the tropics, poleward drift in the upper troposphere, slow sinking in the extratropics and an equatorward drift in the planetary boundary layer. This zonally symmetric parcel circulation is important for transport of water vapor, momentum, and heat

across latitude circles, but represents only a small deviation from the generally west-to-east directed (zonal) winds.

Because the Equator-to-Pole temperature decrease does not occur uniformly but tends to be concentrated in the subtropics, the zonal winds are also concentrated in the jet stream, a narrow band of strong westerly winds in the upper troposphere that encircles the Earth at an average latitude of about 30° . The association of the jet stream with a strong meridional temperature gradient is a consequence of the thermal wind relationship (eqn [9]), which states that eastward-directed winds must increase rapidly with height where the temperature decreases rapidly in latitude.

The concentration of the meridional temperature gradient (and potential vorticity gradient) in the subtropical jet stream cannot be understood by considering the zonally symmetric circulation forced by solar heating, but rather represents a complex interaction between the symmetric circulation and the disturbances that characterize weather and climate. Thus, the study of atmospheric wave disturbances is one of the primary areas of dynamic meteorology.

Atmospheric Waves

Waves in the atmosphere are motions that can transmit energy and momentum without material transport of air parcels. Most weather disturbances are associated with one or more types of atmospheric wave. Atmospheric waves result from a balance between the inertia of the atmosphere and a restoring force. In acoustic waves, for example, oscillations in the pressure gradient force are balanced by parcel accelerations along the direction of phase propagation. Such waves are longitudinal waves in the sense that the fluid parcel oscillations are parallel to the direction of propagation. Most meteorologically important waves, however, are transverse waves in which the parcel oscillations are perpendicular to the direction of phase propagation. Examples of such waves are buoyancy waves, inertia waves, and Rossby waves.

Buoyancy Waves

The vertical stratification of the atmosphere causes a fluid parcel that is displaced vertically to experience a restoring force due to its buoyancy; the resulting coherent oscillations in the pressure, temperature, and wind fields is called a buoyancy wave, or gravity wave. The structure of an eastward-propagating buoyancy wave, excited from below, is shown in Figure 4. Phase lines, defining the maxima in the perturbation pressure and temperature fields, tilt towards the east with height, and propagate eastwards and downwards in time. However, the flux of energy (measured by the correlation between the pressure and vertical velocity perturbations) is directed upwards, parallel to the lines of constant phase. There is also an upward flux of eastward momentum in this case since positive vertical perturbations are in phase with eastward horizontal velocity perturbations, and vice versa. Thus, buoyancy waves provide an important mechanism for vertical transport of momentum in the atmosphere.

The frequency, ω , of a buoyancy wave is related to the angle, α , of the phase lines to the local vertical by the formula

Figure 4 Cross-section showing phases of the pressure, temperature, and velocity perturbations for an internal gravity wave. Thin arrows indicate the perturbation velocity field, blunt solid arrows the phase velocity. Shading shows region of upward motion.

$\omega = N \cos \alpha$, where N is again the buoyancy frequency. Thus, high-frequency buoyancy waves have energy propagation that is closer to the vertical than do low-frequency buoyancy waves. An important special case of buoyancy waves are lee waves formed when air in a stable atmosphere is forced to ascend over a mountain barrier. Oscillations that are induced by the forced uplift may continue several wavelengths downstream of the mountain.

When sufficient moisture is present, condensation may occur in the updraft portions of the waves, leading to regularly spaced bands of cloud in the lee of the mountain. In this case the waves are stationary with respect to the ground but propagate relative to an observer moving with the mean wind.

Rossby Waves

The most important class of large-scale atmospheric waves are called planetary waves, or Rossby waves. These waves are characterized by oscillations in the rotational part of the horizontal wind that are parallel to the horizontal gradient in the potential vorticity. The simplest example of a Rossby wave occurs in a barotropic atmosphere. A barotropic atmosphere is one in which potential temperature is constant on each pressure surface so that $\partial\theta/\partial z$ in eqn [10] is independent of horizontal position. Potential vorticity conservation then reduces to conservation of absolute vorticity following the motion:

$$\frac{D}{Dt}(\zeta + f) = 0 \quad [11]$$

The mechanism of Rossby wave propagation can be understood by considering a tube of fluid parcels that at time t_0 is motionless and lies parallel to a latitude circle. In that case $\zeta(x, t_0) = 0$. If the tube is given a small sinusoidal meridional

displacement $\eta(x, t_0)$ at the initial time, then from eqn [11] at a later time t_1 the relative vorticity will be given by:

$$\zeta(x, t_1) = f_{t_1} - f_{t_0} = -\beta\eta(x, t_1) \quad [12]$$

where $\beta \equiv df/dy$, the rate of increase of the Coriolis parameter with latitude. Since β is positive, it is evident from eqn [12] that the relative vorticity perturbation will be positive for a southward displacement and negative for a northward displacement. Since positive relative vorticity corresponds to a counterclockwise rotation and negative relative vorticity corresponds to a clockwise rotation, the induced perturbation velocities will tend to produce meridional displacement of the tube of fluid parcels to the west of the original displacement, as illustrated in Figure 5. By this mechanism, the originally wavy displacement propagates westwards, perpendicular to the north-south displacement of the fluid parcels.

Quantitative analysis of the relationship of the wave frequency to the horizontal scale reveals that Rossby waves are highly dispersive (i.e., their phase speeds are strongly dependent on the wavelength). In Cartesian coordinates the zonal (eastward) phase speed relative to the ground has the form:

$$c_x = \bar{U} - \beta(L_x^2 + L_y^2)/(4\pi^2) \quad [13]$$

Here $\bar{U}$ is the mean eastward wind, L_x is the zonal wavelength and L_y is the meridional wavelength. Thus, Rossby waves propagate westwards relative to the mean wind with phase speeds that increase rapidly as the wavelength increases. For waves corresponding to typical extratropical storms with wavelengths of a few thousand kilometers, the Rossby wave phase speed is typically less than 10 m s^{-1} , which is less than the mean wind speed. Thus, relative to the ground, such disturbances tend to move eastwards, but more slowly than the average eastward wind speed.

Equation [13] also shows that Rossby waves that are stationary relative to the ground ($c_x = 0$) can exist only when the mean zonal flow is positive (i.e., eastwards). Stationary

Rossby waves are excited in midlatitudes when westerly winds encounter largescale mountain barriers and are displaced meridionally during ascent over the barrier. This process is a primary reason why large-scale stationary cyclonic disturbances are commonly observed to the lee of the Rocky and the Himalayan mountain ranges.

Baroclinic Waves

Barotropic Rossby waves are generated by conversion of the kinetic energy of the zonal flow into kinetic energy of the waves. They do not involve any conversion of potential energy to kinetic energy. Such energy conversion can occur only in the presence of baroclinicity, that is, variations of potential temperature on isobaric surfaces. Baroclinic energy conversion is responsible for the growth and maintenance of most large-scale weather disturbances.

When the latitudinal gradient of the zonal wind in the jet stream is sufficiently strong that the meridional gradient of potential vorticity on a constant potential temperature surface is locally reversed, or when there is a nonvanishing gradient of potential temperature at the surface of the Earth, the equations of motion linearized about a zonally symmetric basic state have solutions in the form of exponentially growing wave disturbances. These baroclinically unstable waves have growth rates, structure, and scales typical of those observed in developing extratropical cyclones. They are quasi-geostrophic in the sense that the geostrophically balanced rotational component of the wind field strongly dominates over the ageostrophic divergent component. The latter is, however, crucial in the energy cycle by which the waves convert potential energy associated with the Pole-to-Equator temperature gradient into disturbance kinetic energy.

Baroclinic instability provides a mode whereby infinitesimal disturbances may be amplified into large-amplitude storms. In many situations, however, it appears that weather disturbances may develop rapidly from preexisting upper-level potential vorticity anomalies in the absence of baroclinic instability. As in baroclinic instability, the growth of storms from upper-level potential vorticity anomalies is associated with conversion of potential energy to kinetic energy in association with the ageostrophic secondary flow induced by adjustments towards thermal wind balance.

Equatorial Waves

In the equatorial region there is a special class of weather-producing waves that combine some of the characteristics of gravity waves and of Rossby waves. Equatorial waves are trapped in latitude, that is, they propagate along the Equator with amplitudes decreasing with latitude. In some circumstances they may also propagate energy and momentum vertically. Two important examples of equatorial waves are the equatorial Kelvin wave and the Rossby-gravity wave. The Kelvin wave has pressure and zonal velocity perturbations symmetric about the Equator, and negligible meridional velocity component. It propagates eastwards, with vertical structure identical to the eastward-propagating buoyancy wave shown in Figure 4, and is an important source of eastward momentum for the equatorial stratosphere.

Figure 5 Perturbation vorticity field (+ and -) and induced velocity field (dashed arrows) for a meridionally displaced tube of fluid parcels, showing the mechanism for Rossby wave propagation. Heavy wavy line shows initial perturbation of the tube, light wavy line shows westward displacement of the wave perturbation due to advection by the induced velocity field. From Holton, J.R., 1992. *Introduction to Dynamic Meteorology*. Academic Press, New York.

Rossby-gravity waves are waves that combine characteristics of Rossby waves and gravity waves. They have meridional wind distributions symmetric about the Equator and zonal wind and pressure distributions antisymmetric about the Equator. Away from the Equator the wind and pressure distributions in the Rossby-gravity wave are nearly geostrophic, but near the Equator there are strong departures from geostrophic balance. Rossby-gravity waves propagate westwards relative to the mean flow. They are associated with equatorial weather disturbances, and are also a significant source of westward momentum for the equatorial stratosphere.

Mesoscale Disturbances

If an air parcel is saturated, upward displacement will cause water vapor to condense and release its latent heat of condensation; potential temperature is then no longer conserved, but increases following the parcel motion. If this increase is greater than the potential temperature gradient of the background atmosphere, the atmosphere is said to be conditionally unstable. That is, it is stable with respect to unsaturated parcel displacement but unstable with respect to saturated parcel displacements. The convective storms associated with cumulonimbus clouds can occur only when the atmosphere is conditionally unstable, sufficient moisture is present, and sufficient lifting occurs to bring air parcels to

saturation. The processes that organize convection into mesoscale convective systems are not completely understood. Mesoscale convective systems take a variety of forms. Among these are hurricanes, squall lines, and supercell thunderstorms. In all cases the release of latent heat by convective clouds is the primary energy source, but the character of the largescale environmental flow is generally important for determining the mode of organization for mesoscale systems.

Acoustic Waves

KE Gilbert, University of Mississippi, University, MS, USA

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

A brief overview of basic acoustic wave propagation is given, followed by a discussion of refraction and diffraction of audible sound in realistic daytime and nighttime atmospheres. Numerical examples show the effect of atmospheric turbulence on sound propagation in an upward-refracting (daytime) unstable atmosphere and a downward-refracting (nighttime) stable boundary layer. Experimental results for pulse propagation in a stable nighttime boundary layer with internal gravity waves are presented and discussed. Finally, remote sensing of the atmosphere using a sodar and a radio acoustic sounding system is briefly discussed. A grayscale plot from a sodar is presented and explained. The plot shows the evolution of the atmospheric boundary layer over a diurnal cycle.

Introduction

This article is concerned with acoustic waves in the atmosphere. Owing to space constraints, the discussion is limited to audible acoustic waves (sound waves). Hence, two important topics – ultrasound (above audible) and infrasound (below audible) – are not discussed. Further, in order to provide a more in-depth discussion of the effect of the atmospheric boundary layer on sound waves, some traditional topics such as ground effects, nonlinear effects, and noise control are omitted. The interested reader should refer to the resources cited under the Further Reading section for information on aspects of acoustic waves not covered here.

At the atomic level, the Earth's atmosphere is a collection of gas molecules, mainly nitrogen and oxygen, bound to the planet by gravity. The microscopic properties of the atmosphere are thus described by the kinetic theory of gases and quantum mechanics. In contrast, at the macroscopic level, the atmosphere can be regarded as a fluid, and, in principle, can be described by the equations of fluid dynamics. Both points of view, molecular and fluid dynamical, are needed to fully understand the generation, propagation, and absorption of the disturbances in the atmosphere that are familiar to us as acoustic waves or 'sound.'

Unlike wave motion on a stretched string or ripples on the surface of water, acoustic waves in the atmosphere have no direct visual representation. Consequently, one must in general rely heavily on a mathematical description. It is useful, nevertheless, to try to connect the mathematical description of sound with an intuitive, physical picture, even if the picture is an approximate representation of reality. Hence, for purposes of visualization, one can schematically represent a planar acoustic wave as shown in Figure 1. In Figure 1(a), regions of compression (positive pressure relative to the ambient background pressure) and regions of rarefaction (negative pressure relative to the ambient background pressure) are indicated schematically by the density of points. Closely spaced points represent a compression, and less closely spaced points represent a rarefaction. The vertical lines in Figure 1(b) indicate regions of constant pressure that are called 'wavefronts.' The maximum pressure regions are indicated by solid vertical lines and the minimum pressure regions by dashed lines. The horizontal line perpendicular to the wavefronts is called an acoustic

'ray.' Acoustic rays are a concise way to indicate the travel paths taken by acoustic wavefronts as they propagate through space. In Figure 1(c), the regions of compression and rarefaction, often called the 'acoustic' pressure, are shown moving to the right with a speed c , which for dry air is 331.6 m s^{-1} at 0°C . For a compact representation of the pressure wave one could, for example, omit the wavefronts and simply show an acoustic ray moving to the right with a speed c .

For sinusoidal pressure variations, a planar acoustic wave can be represented mathematically as $p = p_0 \cos(kx - \omega t + \theta)$, where p_0 is the acoustic pressure amplitude, and the entire argument of the cosine is called the 'phase' of the wave. The angular frequency, ω , is $2\pi f$, where f is the frequency in cycles

Figure 1 Visualization of a planar acoustic wave moving to the right at speed c . (a) Schematic representation of regions of compression (denser points) and regions of rarefaction (less dense points). (b) Wavefronts (regions of constant pressure); maximum and minimum pressure regions are represented, respectively, by solid and dashed vertical lines. An acoustic ray is drawn perpendicular to the wavefronts. (c) Pressure variation in space at two instants of time for a sinusoidal plane wave of the form $p = p_0 \cos(kx - \omega t + \theta)$.

per second or, more commonly, in hertz (Hz). The wave number k is $2\pi/\lambda$, where λ is the wavelength shown in Figure 1(c). Since $\lambda f = c$, the wave number can also be written as ω/c . The quantity θ is called the 'phase angle' and gives the phase of the wave at $x = 0$ and $t = 0$.

The compressions and rarefactions in an acoustic wave cause variations in density and temperature that also propagate with the wave. For all three quantities – pressure, temperature, and density – the acoustic amplitude is extremely small relative to the ambient background. For example, p_0 might be 0.1 Pa or approximately one millionth of the nominal atmospheric pressure.

The Acoustic Wave Equation

As noted above, acoustic waves in the atmosphere can be viewed as small disturbances on an ambient background fluid, just as water waves are seen as disturbances on a calm surface. For the extremely small pressure perturbations typical of sound, the equations of fluid dynamics can be linearized to arrive at the 'acoustic wave equation,' which is the conventional mathematical description of acoustic pressure waves. In one dimension, the acoustic wave equation is given by eqn [1], where p is the acoustic pressure, x is the distance, and t is the time.

$$\frac{\partial^2}{\partial x^2} p = \frac{1}{c^2} \frac{\partial^2}{\partial t^2} p \quad [1]$$

The general solution to eqn [1] is of the form $p(x, t) = p_R(x - ct) + p_L(x + ct)$, where $p_R(x - ct)$ is a right-going wave and $p_L(x + ct)$ is a left-going wave. The right-going wave, for example, could be a transmitted pulse, and the left-going wave could be an echo. Continuous waves as well as pulses satisfy the wave equation. For example, since $c = \omega/k$, the sinusoidal pressure wave discussed above satisfies the one-dimensional wave equation. Moreover, as indicated in Figure 2, any function of $(x - ct)$ or $(x + ct)$ satisfies eqn [1]. Further, the perturbations in density and temperature associated with an acoustic pressure wave satisfy the same wave equation as the acoustic pressure except that, instead of pressure, the variable is density or temperature, respectively.

The three-dimensional form of eqn [1] is eqn [2], where (x, y, z) are Cartesian coordinates.

$$\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \right) p = \frac{1}{c^2} \frac{\partial^2}{\partial t^2} p \quad [2]$$

Figure 2 Solutions to the one-dimensional wave equation. The function $p_R(x - ct)$ is a right-going solution and the function $p_L(x + ct)$ is a left-going solution. The complete solution is the superposition of the left- and right-going solutions.

Figure 3 Schematic representation of an out-going spherical wave. The circles are the wavefronts and the straight lines are acoustic rays. The solid and dashed circles denote, respectively, wavefronts for maximum and minimum pressure.

For a symmetrical source, such as a small explosion high above the ground, the three-dimensional wave equation has spherical symmetry and can be written as eqn [3].

$$\frac{\partial^2}{\partial r^2} (rp) = \frac{1}{c^2} \frac{\partial^2}{\partial t^2} (rp) \quad [3]$$

Here $r = \sqrt{x^2 + y^2 + z^2}$. By comparing the form of eqn [3] with that of eqn [1], one can deduce that the general solution of eqn [3] is given by eqn [4], in which r_{ref} is an arbitrary reference distance, generally taken to be 1 m in the meter-kilogram-second (MKS) system.

$$p(x, t) = \left(\frac{r_{\text{ref}}}{r} \right) [p_{\text{OUT}}(r - ct) + p_{\text{IN}}(r + ct)] \quad [4]$$

The quantities $(r_{\text{ref}}/r)p_{\text{OUT}}(r - ct)$ and $(r_{\text{ref}}/r)p_{\text{IN}}(r + ct)$ are out-going and in-going spherical waves, respectively. Note that the spherical wave solution has the same mathematical form as the plane-wave solution except that the amplitude falls off as $1/r$.

For a source far away from boundaries, the acoustic pressure is given by an out-going wave having the same shape in the time domain as the source function. For example, for a time-harmonic source, the acoustic field is a traveling sinusoidal wave of the form $p = p_0(r_{\text{ref}}/r) \cos(kr - \omega t + \theta)$, where p_0 is the pressure amplitude at the reference distance. Pictorially, an out-going spherical wave can be represented as shown in Figure 3, where pressure maxima and minima of the wavefronts are represented, respectively, by solid lines and dashed lines. The radial lines perpendicular to the wavefronts are acoustic rays.

Sound Pressure Levels and Decibels

Acoustic pressure amplitudes encountered in practice typically vary over several orders of magnitude. Consequently, it has become conventional to use a logarithmic scale to describe the amplitudes. For continuous waves, the amplitude of interest is the root-mean-square pressure amplitude, p_{rms} , and is referenced to some standard reference pressure p_{ref} . For pulses, some

'peak' pressure is often chosen. In either case, a logarithmic amplitude measure called the 'sound pressure level' (SPL) is commonly used, defined by eqn [5].

$$\text{SPL} \equiv 10 \log_{10} \left(\frac{p_{\text{rms}}^2}{p_{\text{ref}}^2} \right) = 20 \log_{10} \left(\frac{p_{\text{rms}}}{p_{\text{ref}}} \right) \quad [5]$$

The pressure of interest is denoted here as the rms pressure, but could be any pressure, depending on the application. Although SPL is actually a dimensionless quantity, one refers to the 'units' as decibels (dB), referenced to a reference pressure, p_{ref} . In atmospheric acoustics, the reference level is usually chosen to be 2×10^{-5} Pa or 20 μPa , which is the approximate threshold of hearing. Note that with the above conventions, the SPL for 20 μPa is 0 dB.

The frequency range for audible sound for the human ear is from approximately 20 Hz to approximately 20 kHz. Typical SPLs for sounds in the audible range are given in Table 1.

In addition to being used as a measure for absolute pressure, decibels are also used to describe relative changes in pressure. For example, if a pressure amplitude decreases with distance by a factor of 10, it is conventional to say that, over the distance, the acoustic pressure has decreased by $20 \log_{10}(10) = 20$ dB. If one pressure amplitude were 100 times greater than another, one would say the first pressure was 40 dB greater than the second pressure.

To express in decibels the variation of the rms pressure, $p_{\text{rms}}(r)$, with distance, it is conventional to define the SPL at $r = r_{\text{ref}}$ as the 'source level' (SL) as in eqn [6] and to define the decibel decrease in acoustic pressure with distance as the 'transmission loss' (TL) as in eqn [7].

$$\text{SL} \equiv 20 \log_{10} \left(\frac{p_{\text{rms}}(r_{\text{ref}})}{p_{\text{ref}}} \right) \quad [6]$$

$$\text{TL} \equiv -20 \log_{10} \left(\frac{p_{\text{rms}}(r)}{p_{\text{rms}}(r_{\text{ref}})} \right) \quad [7]$$

In these equations, as noted previously, the reference distance, r_{ref} , is 1 m in the MKS system. (Note that since pressure usually decreases with distance, TL is usually positive.) Using the above definitions for SL and TL, one can write the SPL at a distance r from the source as $\text{SPL} = \text{SL} - \text{TL}$. For example, in MKS units, the rms pressure amplitude for a spherically spreading wave can be written as $p_{\text{rms}}(r) = p_1/r$, where p_1 is the rms pressure at 1 m. Thus, for a spherically spreading wave, the SL is $20 \log_{10}(p_1/p_{\text{ref}})$ and the TL is simply $20 \log_{10}(r)$.

Table 1 Representative list of audible sound pressure levels

Sound	SPL (dB)
Threshold of hearing	0
Leaves rustling	20
Quiet conversation	40
Normal conversation	60
Average street traffic	80
Diesel truck (at 10 m)	90
Jet takeoff (at 10 m)	120
Threshold of pain	140

In general, the TL is not a simple function and must be computed numerically. With numerical computations, it is often useful, for plotting purposes, to subtract the TL due to spherical spreading, that is, to subtract $20 \log_{10}(r)$. Such a convention is equivalent to giving the SPL relative to a spherically spreading wave, and hence is given the name 'relative SPL.' Thus, by definition, the relative SPL for a spherically spreading wave is 0 dB. Expressed as a relative SPL, an SPL above or below that for spherical spreading will be, respectively, greater than or less than zero.

The Speed of Sound in the Atmosphere

To a good approximation, the atmosphere can be treated as an ideal gas, and the acoustic pressure variations in it can be treated as adiabatic; that is, there is no heat flow from the high-pressure (hotter) regions to the low-pressure (cooler) regions. For an ideal gas and adiabatic compression (or rarefaction), the speed of sound is given by $c = \sqrt{\gamma RT}$, where $\gamma = 1.40$ is the ratio of the constant-volume specific heat for air, c_V , to the constant-pressure specific heat, c_P . The quantity $R = 286.69 \text{ J kg}^{-1} \text{ K}^{-1}$ is the gas constant for dry air, and T is the absolute temperature (K). With an ideal gas model, the theoretical value for c at 0°C (273.16 K) is 331.1 m s^{-1} , which is in excellent agreement with the experimental value of 331.6 m s^{-1} given earlier. For values of T not far from 0°C , the square root expression for the speed of sound can be expanded linearly and written approximately as $c = (331 + 0.6T_C) \text{ m s}^{-1}$, where T_C is the temperature in degree Celsius. Thus, for an increase in temperature of 1°C , the speed of sound increases by 0.6 m s^{-1} .

Absorption of Sound in the Atmosphere

In addition to the decrease in pressure amplitude of an acoustic wave due to propagation effects such as 'geometrical' spreading (e.g., spherical spreading), the amplitude is also reduced by atmospheric absorption. A sound wave propagating through 'clean' air (no solid particles) is attenuated owing to two basic mechanisms:

- classical losses due to momentum transfer across a velocity gradient (viscosity) and heat flow across a temperature gradient and
- quantum-mechanical losses due to relaxation processes, mainly relaxation of rotational and vibrational states in nitrogen and oxygen molecules.

For both mechanisms, the effects of absorption can be represented by an absorption coefficient, α , which has units of m^{-1} . The absorption coefficient enters via an exponential, so that the pressure is given by $p = p_0 e^{-\alpha s}$, where p_0 is the unattenuated pressure amplitude and s is the distance the wave has traveled. To indicate the choice of the Napierian base, e , the attenuation coefficient is, by convention, said to have units of nepers m^{-1} . The corresponding attenuation coefficient, a , for decibels (base 10) is $a = 20\alpha \log_{10}(e) = 8.686\alpha$, and, by convention, has units of dB m^{-1} .

Experimental and theoretical studies indicate that the total absorption coefficient can be represented as a sum of

absorption coefficients, with each distinct physical process having its own unique coefficient. That is, the total absorption coefficient α_T can be written as $\alpha_T = \sum_i \alpha_i$, where α_i is the absorption coefficient associated with a particular mechanism. For example, the component of sound absorption due to viscosity is given by eqn [8], in which ω is the angular frequency, c is the speed of sound, ρ_0 is the density of air, and μ is the coefficient of viscosity of air.

$$\alpha_{\text{vis}} = \frac{\omega^2}{2\rho_0 c^3} \frac{4\mu}{3} \quad [8]$$

Since the compressed regions in an acoustic wave are slightly hotter than the ambient temperature, and the expanded regions are slightly cooler, a small amount of heat flows from the compressions to the rarefactions. The conduction of heat converts the organized motion associated with the sound wave into random thermal motion of the gas molecules. Because the heat flow lowers the temperature of the compressions and raises the temperature of the rarefactions, both the pressure maxima and minima are reduced. The reduction manifests itself as a decay of the acoustic wave with distance. The component of absorption due to thermal conduction is given by eqn [9], where κ is the coefficient of thermal conductivity in $\text{J (kg mol)}^{-1} \text{K}^{-1} \text{kg m}^{-1} \text{s}^{-1}$.

$$\alpha_{\text{TH}} = \frac{\omega^2}{2\rho_0 c^3} (\gamma - 1) \frac{\kappa}{\gamma c_V} \quad [9]$$

In addition to the energy loss due to classical mechanisms (viscosity and heat conduction), energy can also be lost via quantum-mechanical ‘relaxation’ processes involving the internal degrees of freedom (rotation and vibration) of oxygen and nitrogen molecules. The transfer of translational energy to and from internal degrees of freedom takes place through an extended sequence of molecular collisions, so there is a time delay associated with the energy transfer. Because of the time delay, relaxation processes cause energy to be lost from the organized translational motion that constitutes the acoustic wave. As a result, just as with the classical mechanisms, the pressure amplitude of the wave decreases as the wave propagates.

For any particular relaxation process, the associated absorption coefficient has the general form of eqn [10].

$$\alpha = \frac{\pi s_v}{c} \frac{f^2/f_r}{1 + (f/f_r)^2} \quad [10]$$

In eqn [10], s_v is the relaxation strength (in nepers), c is the sound speed, f is the frequency, and f_r is called the ‘relaxation’ frequency. The relaxation frequency is the frequency for maximum absorption and is roughly the reciprocal of the characteristic time delay for the transfer between kinetic energy and internal energy of the gas molecules.

For air, there are three important relaxation processes: (1) O_2 vibration, (2) N_2 vibration, and (3) N_2 rotation. The relaxation frequency for N_2 rotational relaxation is very high, so that, below 10 MHz, the denominator in eqn [10] is approximately unity. Thus, N_2 rotational relaxation varies as f^2 and can be combined with the classical absorption coefficient. If one denotes the classical-plus-rotational absorption coefficient (i.e., the coefficient for viscosity, heat flow, and N_2 rotation) as α_C , the absorption coefficient for O_2 vibration as

Figure 4 Components and general behavior of the total absorption coefficient for air. The contributions to the total absorption (T) are the classical plus N_2 rotation (C), the O_2 vibration (O), and the N_2 vibration (N). Reproduced with permission from Bass, H.E., 1991. Atmospheric acoustics. In: Trigg, G.L., (Ed.), Encyclopedia of Applied Physics vol. 2, Wiley-VCH Verlag GmbH & Co. KGaA, pp. 145–179.

α_O , and the absorption coefficient for N_2 vibration as α_N , then the total absorption coefficient α_T for air can be written as eqn [11].

$$\alpha_T = \alpha_C + \alpha_O + \alpha_N \quad [11]$$

Figure 4 shows the total absorption coefficient, α_T , together with the components, α_C , α_O , and α_N . Note that below about 10 000 Hz the absorption is dominated by vibrational relaxation. Further, note that, above about 1000 Hz, atmospheric absorption is significant for propagation distances of a kilometer or more, which accounts for the lack of long-range propagation of high-frequency sound.

Refraction of Sound in the Atmosphere

The spherical wavefronts and associated rays shown in Figure 3 represent acoustic waves radiating from a point source in an atmosphere with a constant temperature, and hence a constant sound speed. With a constant sound speed, acoustic ray trajectories are straight lines. In reality, however, the atmospheric temperature is never constant in space or time. Consequently, the speed of sound is not constant but varies spatially and temporally. In a typical daytime situation, the temporally averaged temperature is independent of range but decreases with height (‘lapse’ condition). Thus, on average, the sound speed decreases with height, and sound rays curve upward, as shown in Figure 5. The ray paths shown are for a sound speed that decreases linearly with

Figure 5 Acoustic rays and shadow zones for an upward-refracting daytime atmosphere. For clarity, rays that are reflected off the ground are not shown. Reproduced with permission from Bass, H.E., 1991. Atmospheric acoustics. In: Trigg, G.L., (Ed.), Encyclopedia of Applied Physics vol. 2. Wiley-VCH Verlag GmbH & Co. KGaA, pp. 145–179.

height. (For the simple case of linear variation, the ray paths are arcs of circles.)

For a general sound speed variation in a stratified atmosphere (i.e., no horizontal variation), ray paths are governed mathematically by Snell's law, which states that the quantity $c(z)/\cos \theta(z)$ is invariant, where at a height z , the quantities $c(z)$ and $\cos \theta(z)$ are, respectively, the sound speed and the cosine of the angle of a ray with respect to horizontal. Thus, Snell's law says that if $c(z)$ decreases with height, $\cos \theta(z)$ must also decrease, so that the ray bends upward. In general, acoustic rays bend toward regions of lower sound speed and away from regions of higher sound speed. The bending of acoustic rays is given the name 'refraction.'

The physical basis for refraction can be understood using the situation in Figure 5. Consider a small section of wavefront associated with a ray that leaves the source nearly parallel to the ground. For a small enough section, the wavefront is nearly planar and nearly vertical. Since the sound speed decreases with height, the lower portion of the wavefront travels faster than the upper portion, causing the wavefront to turn upward. In terms of rays, we would say that the ray is refracted upward due to the decrease in the sound speed with height.

Refraction of acoustic waves is caused by spatially varying wind as well as by spatially varying temperature. The effect of the wind on acoustic waves can be accounted for approximately by defining an 'effective' sound speed, c_e , which is the previously defined 'adiabatic' sound speed, $c_a = \sqrt{\gamma RT}$, plus the component of the vector wind in the direction of propagation. For example, let $\hat{r}$ be a unit vector pointing from the source to a receiver. Then, if the vector wind is denoted as $\mathbf{v} \equiv (v_x, v_y, v_z)$, the effective sound speed is given by $c_e = c_a + \hat{r} \cdot \mathbf{v}$, where $\hat{r} \cdot \mathbf{v}$ is the component of the vector wind in the direction of sound propagation. In general, near the ground, the horizontal wind speed increases with increasing height. For upwind propagation of sound, therefore, the horizontal wind progressively reduces the effective sound speed with increasing height. For downwind propagation, the effect is reversed. That is, with downwind propagation of sound, the

horizontal wind progressively increases the effective sound speed with increasing height. In the daytime, for example, where the temperature and adiabatic sound speed decrease with height, upwind propagation adds to the upward refraction already present. Downwind, if the wind speed gradient is sufficiently large, the horizontal wind can overcome the upward refraction due to the daytime temperature profile and lead to downward refraction. The ray paths for upwind and downwind propagation are illustrated in Figure 6. For propagation directly across the wind, there is little effect due to the wind, but upward refraction persists because of the decreasing temperature with height.

Hereafter in this article, the terms 'sound speed' and 'effective sound speed' are used interchangeably, so that it is always assumed that the effect of wind is included. When the wind is not included, the sound speed is referred to as the 'adiabatic sound speed.'

As indicated in Figures 5 and 6, for upward refraction, there is a region called an acoustic 'shadow,' where no acoustic rays can penetrate. In the shadow region, the acoustic levels are much lower than the SPL one would expect with spherical spreading alone. Because of upward refraction, daytime SPLs for a near-ground source fall off dramatically with horizontal distance as one enters the shadow region, which, for strong upward refraction, can be within 100–200 m of the source.

At night, in contrast to the daytime situation, ground-to-ground propagation is very good. Owing to radiative cooling of the ground, both the near-ground air temperature and the sound speed are lower than at higher altitudes (an 'inversion' condition). As a result, acoustic rays launched near to horizontal (less than about 10° with respect to horizontal) are bent downward, causing sound to be trapped in a 'sound duct' near the ground. Rays launched at steeper angles escape the duct and continue upward (Figure 7). With strong trapping and small ground-bounce loss (e.g., over water) the acoustic field in the near-surface sound duct undergoes approximately cylindrical spreading ($1/\sqrt{r}$) instead of spherical spreading ($1/r$).

Figure 6 Acoustic rays and shadow zone for an atmosphere that is upward refracting in the upwind direction and downward refracting in the downwind direction. For clarity, rays that are reflected off the ground are not shown. Reproduced with permission from Bass, H.E., 1991. Atmospheric acoustics. In: Trigg, G.L., (Ed.), Encyclopedia of Applied Physics vol. 2. Wiley-VCH Verlag GmbH & Co. KGaA, pp. 145–179.

Figure 7 Acoustic rays for a downward-refracting nighttime atmosphere. Rays launched at small angles with respect to the horizontal (less than about 10°) are trapped in a 'sound duct' near the ground and can propagate to ranges of several kilometers. For steeper launch angles, the rays escape the duct and continue upward.

As a consequence of daytime upward refraction and nighttime downward refraction, noise sources that are not generally heard during the day can often be easily heard at long distances (e.g., several kilometers) at night. The long-range propagation of acoustic waves at night makes noise control much more difficult than during the day.

Diffraction of Acoustic Waves in the Atmosphere

As discussed above, one can approximately represent an acoustic field in terms of wavefronts whose propagation directions (i.e., rays) are governed by refraction. Such a representation is useful visually and can be valid computationally when the acoustic wavelengths are much smaller than the smallest sound-speed structure in the atmosphere. The main effect left out in the so-called 'ray theory' of sound propagation

is the wave phenomenon known as 'diffraction.' Diffraction is responsible for the well-known ability of sound to 'bend' around corners and obstacles. In outdoor sound propagation, diffraction fills in gaps in the acoustic field that would be present in a purely ray-based representation. Full-wave solutions to the wave equation (usually numerical) automatically include both diffraction and refraction.

Because of diffraction, every acoustic field has an intrinsic smallest possible scale length that is roughly a quarter of the smallest wavelength present in the field. Owing to the scale limitation, there can be no sharp edges in the acoustic field. For example, instead of the sharp shadow boundary obtained with rays (Figures 5 and 6), a smooth, diffuse boundary is obtained when diffraction is included. Such a situation is illustrated in Figure 8, which shows a numerical solution of the wave equation for a 500 Hz point source in an upward-refracting atmosphere. The color plot in the figure, which is for the relative SPL

Figure 8 Numerical solution for the sound field in an upward-refracting daytime atmosphere without turbulence. Owing to diffraction, the edge of the shadow boundary is diffuse. The color plot shows the relative SPL as a function of range and height. (Note that the vertical scale is much less than the horizontal scale, so that the actual propagation angles with respect to the horizontal are much smaller than shown.)

as a function of range and height, shows the effects of both diffraction and refraction. The edge of the shadow boundary in [Figure 8](#) would become more diffuse at lower frequencies (longer wavelengths), until finally, at very low frequencies, the shadow boundary would not be discernible at the ranges shown.

When the atmosphere is downward refracting (e.g., at night), the presence of diffraction again causes a ‘blurring’ of the features of the acoustic field, just as with upward refraction. There are no sharp discontinuities in the structure of the acoustic field. Rather, because of the finite wavelengths in the acoustic field, the changes in the field are continuous and smooth, as shown in [Figure 9](#), which is also for a 500 Hz point source. In general, the longer the acoustic wavelengths (i.e., the lower the frequency), the smoother the features of the acoustic field.

In addition to limiting the sharpness of the acoustic field, diffraction is responsible for the scattering of acoustic waves from the complex small-scale structure of the real atmosphere. In a realistic model of the atmosphere, the instantaneous temperature and vector wind fields are not smooth but are highly irregular, containing eddies of all sizes. The eddy sizes of most concern for audible sound are in the region called the ‘inertial subrange,’ which typically begins at a few tens of meters and goes down to a few millimeters. In the inertial subrange, the eddy structure is governed by the well-known Kolmogorov spectrum. As a consequence, at any instant of time, the small-scale spatial structure of the sound speed field, which depends on temperature and vector wind, can also be described by a Kolmogorov spectrum. In the daytime turbulent boundary layer, for example, the sound speed can be approximated as a time-independent mean sound speed, $\bar{c}(z)$, that varies only with height, plus a fluctuating part, $\delta c(x, y, z, t)$, that varies with time, horizontal distance, and height. Hence the total sound speed, $c(x, y, z, t)$, can be represented as in eqn [12].

$$c(x, y, z, t) = \bar{c}(z) + \delta c(x, y, z, t) \quad [12]$$

The quantity $\bar{c}(z)$ approximates the slow, large-scale variations in the sound speed profile and $\delta c(x, y, z, t)$ describes the rapid, smaller-scale fluctuations.

As noted earlier, the quantity $\delta c(x, y, z, t)$ follows the same Kolmogorov statistics as do the temperature and wind fluctuations. At a particular instant of time, an approximate ‘snapshot’ of the sound-speed fluctuation field, $\delta c(x, y, z, t)$, can be synthesized by adding together, with random phase, the wave number components for a Kolmogorov spectrum. The result of such a synthesis is shown in two dimensions in [Figure 10](#). Because audible sound has wavelengths comparable in size to small-scale atmospheric structure, it is scattered in all directions as it propagates through inertial-subrange eddies. As a consequence of diffraction, new wavefronts emanate from every eddy, with the strongest scattering occurring in the near-forward direction. The diffracted acoustic waves that are scattered downward act to fill in the shadow region. An example of this phenomenon is shown in [Figure 11](#), which was computed numerically using realistic representations for $\bar{c}$ and δc . With a realistic model for the sound speed, the predicted mean near-ground levels (–20 to –30 dB relative to spherical spreading) in the shadow region (0.2–2 km) are in good agreement with the measured mean sound pressure levels. The relative SPL for a longer-range interval is shown in [Figure 12](#). It is apparent from [Figure 12](#) that, even with scattering into the shadow region, daytime levels near the ground are very low at ranges beyond a few kilometers.

It can be observed in [Figures 11 and 12](#) that the effects of turbulence are most apparent in the shadow region, where the sound levels would be extremely small in the absence of turbulence. Above the daytime shadow region, in the ‘insonified’ region, the levels are much higher, so that the effect of scattering from turbulence is less dramatic, though the effect increases with increasing distance from the source. Similarly, for nighttime propagation in the near-ground acoustic duct, where the mean

Figure 9 Numerical solution for the sound field in a downward-refracting nighttime atmosphere without turbulence. Note that downward refraction ‘traps’ sound in the near-ground acoustic duct. As in [Figure 8](#), the features of the acoustic field are blurred owing to diffraction. The color plot shows the relative SPL as a function of range and height. (Note that the vertical scale is much less than the horizontal scale, so that the actual propagation angles with respect to the horizontal are much smaller than shown.)

Figure 10 A two-dimensional 'snapshot' of small-scale turbulent fluctuations in a sound-speed field synthesized using a Kolmogorov spectrum and random Fourier components. The fluctuation magnitudes are typical of those created by turbulence in the daytime.

Figure 11 Same as Figure 8 except that the small-scale turbulence shown in Figure 10 is included. Note that the effects of turbulence are most apparent in the shadow region. Scattering of acoustic waves from turbulence 'fills in' the shadow region so the levels there are much higher than the no-turbulence case shown in Figure 8.

levels are high, the effect of scattering from turbulence is not as dramatic as in the shadow region above the duct (Figure 13). Further, the nocturnal boundary layer, being more stable, intrinsically has weaker turbulence than the daytime boundary layer. As a consequence, mean sound levels at night near the ground are not affected by turbulence nearly as much as the near-ground daytime levels. However, in contrast to small-scale turbulence, large-scale nocturnal phenomena such as internal gravity waves (IGW) can have a significant effect on long-range

sound propagation (1–3 km) at night. The effects of such large-scale dynamic features on sound propagation are considered next.

Acoustic Pulse Propagation through IGW in the Stable Nighttime Boundary Layer

IGW in the stable nighttime boundary layer are analogous to gravity waves in the ocean. Like the ocean, the nighttime

Figure 12 Same as **Figure 11** except that the range extends to 10 km. Note that even with scattering into the shadow region, daytime sound pressure levels near the ground are very low at ranges beyond a few kilometers.

Figure 13 Same as **Figure 9** except that small-scale turbulence typical of a nighttime atmosphere has been included. Since sound levels are relatively high in the near-ground nocturnal acoustic duct, the effects of small-scale turbulence are less evident than during the daytime.

boundary layer is seldom quiescent, but generally has undulations moving through it at wave speeds typically ranging from about 1 to over 10 m s^{-1} . The wave periods of the undulations usually range from a few minutes to over an hour. These wave speeds and periods correspond to wavelengths ranging from less than a kilometer for the short-period waves to over 5 km for the long-period waves. The fluid displacements in the boundary layer caused by the IGW are primarily vertical. Although the displacement amplitude is zero at the ground surface, in the first 100 m it increases approximately linearly with height, becoming as large as 50–100 m near the top of the boundary layer.

The vertical displacements due to the IGW cause a distortion of the effective sound-speed profile, so that it varies in both space and time. Since the IGW displacement increases with

altitude, the sound-speed profile distortion also increases with increasing altitude. The temporal and horizontal spatial scales of the distortion are governed, respectively, by the periods ($\sim 1\text{--}60 \text{ min}$) and wavelengths ($\sim 0.06\text{--}10 \text{ km}$) of the IGW. Hence, compared to turbulence, the distortion of the effective sound speed profile by IGW is large-scale and slowly varying.

The effect of IGW on nighttime sound propagation is most easily seen in acoustic pulse propagation over distances of 1–3 km. Since, at these ranges, scattering by turbulence is relatively weak, the dominant time-dependent effect on pulse propagation results from the large-scale distortion of the effective sound speed profile caused by the IGW. Thus, the IGW mainly refract (i.e., bend) the sound waves rather than scattering them by diffraction. The degree of refraction varies over time as the IGW move through the nighttime boundary layer.

Figure 14 shows a received acoustic pulse from a propane cannon source at distances of 20 m and 1.7 km. The propagation to 1.7 km shown in the figure is for a reference ('mean') state of the acoustic duct that is created by a temperature inversion in the nighttime boundary layer. Note that the propagation of the pulse in the mean acoustic duct has increased ('dispersed') the pulse length from 6 ms (0.006 s) at 20 m to 100 ms (0.100 s) at 1.7 km, an increase of more than a factor of 15. As is discussed below, the length of the pulse received at 1.7 km is not constant but changes over time as the mean state of the acoustic duct is distorted by the IGW. However, before discussing these pulse length fluctuations, it is helpful to first discuss pulse propagation in the mean acoustic duct.

The pulse spreading (dispersion) in Figure 14 results from the acoustic pulse having different wave speeds over different propagation paths in the atmosphere. As indicated in Figure 15, the first arrival is the direct arrival, which travels high in the boundary layer where the sound speed is higher (note the ray paths and sound speed profiles in Figure 17). The later arrivals (single ground reflection, multiple ground reflections, and low-frequency tail) travel progressively lower in the boundary layer where the sound speed is progressively lower. The low-frequency tail, which is confined to the first 10–20 m above the ground, is slowest and arrives last. In general, the lower a ray travels in the boundary layer, the later it arrives.

Figure 14 Pressure-versus-time records for propane cannon pulses measured at night at distances of (a) 20 m and (b) 1.7 km. Note that over the 1.7 km propagation path, the pulse length increases from 6 ms (0.006 s) to approximately 100 ms (0.100 s). A theoretical treatment of the long range propagation of impulse signals under strongly ducted nocturnal conditions. *Journal of the Acoustical Society of America* 124, 2742–2754.

Figure 15 Pressure-versus-time waveform in Figure 14 labeled with the main pulse arrivals, starting with the first arrival and ending with a low-frequency tail (surface wave). As ray paths, the direct arrival travels highest in the boundary layer, and the low-frequency tail travels the lowest. The intermediate arrivals (single and multiple ground reflections), travel at altitudes between that of the direct arrival and the low-frequency tail. Reproduced with permission from Blom, P., Waxler, R., 2012. Impulse propagation in the nocturnal boundary layer: analysis of the geometric component. *Journal of the Acoustical Society of America* 131, 3680–3690.

The dispersed pulse train shown in Figures 14 and 15 is for a single cannon shot propagating through the mean state of the boundary layer. On the successive shots shown in Figure 16, the acoustic duct has been distorted by IGW. In the distorted duct, the overall pulse shape is maintained, but the length of the pulse changes. As the IGW propagate through the boundary layer, the overall waveform of the received pulse expands and contracts (i.e., the pulse length fluctuates) with a time scale governed by the IGW periods. Figure 16(a)–(d) shows acoustic pulse lengths measured over 33 min. Each individual figure in Figure 16(a)–(d) contains 2 min of data, with the pulses separated by 30 s, starting with the first pulse at the bottom of each figure. The time separation between each individual figure is 11 min. Figure 16(a)–(d) shows that, over 33 min, the acoustic pulse length increases from an initial length of approximately 0.08 s (80 ms) to a length of approximately 0.10 s (100 ms), an increase of 0.02 s (20 ms). Note that the pulse length does not change significantly over intervals of minutes but changes measurably over intervals of tens of minutes or more. The repeatability of the pulses over time intervals of minutes shows two things. First, there is little scattering by turbulence, and second, the acoustic pulses are not significantly affected by the short-period IGW. The variation in the pulse length over tens of minutes shows, in contrast to the short-period IGW, that the long-period IGW do significantly affect that the length of the acoustic pulses.

Figure 16 Pressure-versus-time records for propane cannon pulses propagating in the nighttime boundary layer. The pulse timing is shown on the horizontal axis, with the pulse always beginning at $t = 0$. Each vertical division in the figures is 0.1 Pa, and successive pulses are displaced vertically by 0.2 Pa. Each individual figure shows 2 min of data. The successive pulses in each figure are separated by 30 s, starting with the first pulse at the bottom of the figure. The four figures, (a)–(d), are each separated by 11 min, so that **Figure 16(d)** is for cannon shots made 33 min after those in **Figure 16(a)**. Note that over time intervals of minutes, the pulse lengths do not change significantly, but over time intervals of tens of minutes or greater, the pulse lengths change noticeably.

Figure 17 Analysis of the first and second arrivals for three pulses selected from the same experiment as in Figures 14–16. In the left-most panels, which show the measured pulses (dot-dash lines) and least-squares fits (solid lines), Impulse 1 has the smallest time separation between the first and second arrivals, and Impulse 2 has the largest separation. In Impulse 3, the time separation is intermediate between that of Impulse 1 and 2 and corresponds to the approximate mean state of the nighttime boundary layer. The middle panels show the effective sound speed profiles (solid lines) chosen to give the least-squares best fit to the first and second arrivals shown in the left-most panels. The measured effective sound speed profiles are shown as dots. The ray paths are shown in the right-most panels. Reproduced with permission from Blom, P., Waxler, R., 2012. Impulse propagation in the nocturnal boundary layer: analysis of the geometric component. *Journal of the Acoustical Society of America* 131, 3680–3690.

The variation of the pulse length seen in Figure 16 occurs because the IGW distort the upper part of the effective sound speed profile without significantly affecting the lower part. Consequently, the travel time of the high-altitude first arrival varies considerably more than the travel times of later arrivals. The net result is that the pulse stretches and contracts over time, with the largest variation occurring over a time scale of tens of minutes. As noted above, these long-period fluctuations of the pulse length are caused by the long-period IGW.

The above ideas are illustrated quantitatively in the detailed analysis of the first and second arrivals for the three selected pulses shown in Figure 17. The pulses were selected from data taken during the same experiment as in Figure 16. For each pulse, the effective sound speed profile was fitted using a least-squares method so that the predicted travel times matched the measured travel times. (The first arrival always starts at $t = 0$.) The solid line is the least-squares fit for the sound speed profile, and the dots are the directly measured sound speed values. Note that the smallest time separation occurs for Impulse 1, while the largest separation is for Impulse 2. Impulse 3 is intermediate between the two. The corresponding sound speed profile for Impulse 3 can be considered the reference or ‘mean’ effective sound speed profile. Since the sound speed changes are only a few meters per second, the ray paths are essentially the same for all three pulses, but the cumulative effect on travel time over a distance of 1.7 km is significant. As pointed out earlier, the variation with time of the relative travel times is due primarily to the greater distortion of the upper part of the effective sound

speed profile, which in turn mainly affects the travel time of the first arrival.

For Impulse 1, the IGW vertical displacement of the boundary layer is upward, bringing a lower sound speed (from below) upward toward the highest propagation path, thus slowing down the first arrival (highest ray path in Figure 17). Since the first arrival takes longer, its travel time is closer to that of the second arrival (lower ray path in Figure 17). As a result, the time interval between the first two arrivals for Impulse 1 is the least of the three pulses. For pulse 2, the opposite happens. The IGW displacement is downward, bringing a higher sound speed (from above) downward to the highest propagation path, speeding up the first arrival so that it arrives earlier. Thus the time separation between the first and second arrivals is increased. The upward and downward displacements of the effective sound speed profile can be seen in the least-squares fitted sound speed profiles shown in Figure 17. Note that the time interval between the first two arrivals can be directly correlated with the long-period IGW vertical displacements of the atmosphere.

The experiment discussed above (Figures 14–17) was intermittent. That is, it did not continuously track the pulse length variation for successive cannon shots. Figure 18 is for a different experiment where a propane cannon was fired continuously every 30 s for an extended period of time under stable nighttime conditions. The figure shows a time series for the total pulse length variation (relative to a reference pulse length). The propagation is over a horizontal range of approximately 2.5 km to three different receivers (denoted T1, T2, and T3). Note that, as in Figure 16, over time intervals of

Figure 18 Time series showing the fluctuation of the total acoustic pulse length relative to a reference pulse length as a function of time. The experiment measured pulse propagation in the nighttime boundary layer over a distance of 2.5 km, with propane cannon shots made every 30 s. There were three receivers approximately equidistance from the source. The time series for the three receivers are denoted T1, T2, and T3, respectively. Note that the pulse lengths do not change significantly over time intervals of minutes, but change significantly over time intervals of tens of minutes. Reproduced with permission from Chunchuzov, I., Kulichkov, S., Otrezov, A., Perepelkin, V., 2005. Acoustic pulse propagation through a fluctuating stably stratified atmospheric boundary. *Journal of the Acoustical Society of America* 117, 1868–1879.

minutes, the change in the pulse length is relatively small, but over tens of minutes the pulse length variation is significant. The dominant period is approximately 20–40 min.

The absence of shorter period pulse length fluctuations is partly due to the IGW spectrum and partly due to a ‘filtering’ effect of the experiment itself. The IGW spectrum generally has much larger amplitudes for longer period waves (tens of minutes) than for shorter period waves (minutes). Hence, the long-period distortions of the sound speed profile are much greater than the short-period distortions and generally affect the travel time more. However, even if the IGW spectrum were completely flat, the shorter period variations in the pulse length would be suppressed due to an intrinsic ‘filtering’ effect of the experiment. When the IGW wavelength becomes less than twice the propagation distance, both upward and downward displacements are present along the propagation path. Since upward and downward vertical displacements have opposite effects on the travel time, when both are present, the travel time variations are suppressed, so that the pulse length stays relatively constant. That is, the travel time variations tend to be ‘averaged out’ for IGW wavelengths less than twice the propagation distance (i.e., for shorter period IGW). For a propagation distance of 2.5 km, for example, the response of the acoustic response would begin to be suppressed for IGW wavelengths less than 5 km. The largest suppression is for IGW wavelengths

that ‘fit’ exactly within the propagation distance. If, for instance, the wavelength is exactly the same as the propagation distance, 2.5 km, then there are equal positive and negative fluid displacements along the propagation path. In this case there are approximately equal and opposite changes in the sound speed along all the propagation paths. Since the positive and negative sound speed changes nearly average out for all the propagation paths, the response to an IGW with a 2.5 km wavelength is strongly suppressed.

In reality, the IGW displacement is always a superposition of both short and long wavelengths. However, as noted already, the pulse length responds mainly to the long-wavelength IGW, which have periods of tens of minutes. For these long-wavelength displacements, there is only an upward or downward displacement of the effective sound speed profile along the entire propagation path. Hence, due to both the IGW spectrum and the intrinsic averaging effect, the pulse length variations are dominated by the longer period IGW that have wavelengths greater than twice the propagation distance. These long-period, long-wavelength IGW are the dominant cause of the pulse length variations observed in nighttime pulse propagation experiments.

It is clear from the above discussion that the stretching and compression of an acoustic pulse can be very sensitive to changes in the nocturnal boundary layer. It was seen, for example, that the

time between the first and second arrivals was directly correlated with vertical displacement of the boundary layer along the propagation path of the pulse. Because of the sensitivity of the pulse lengths to IGW, there is the potential for extracting boundary layer information (e.g., the IGW spectrum) from pulse length fluctuations. Such research is a recent and ongoing effort in boundary layer meteorology (see [Further Reading](#) section).

Acoustic Remote Sensing of the Atmosphere

As illustrated above, the sensitivity of acoustic waves to atmospheric wind and temperature variations makes accurate prediction of ground-to-ground sound propagation a challenging problem. Conversely, however, that same sensitivity makes sound a remarkably valuable probe for remotely sensing the complex features of the atmospheric boundary layer. The most widely used acoustic tool for atmospheric sensing is an acoustic pulse-echo probe called a 'sodar,' after the more familiar 'radar,' which is an electromagnetic pulse-echo device. (Note: Sometimes the name 'echosonde' is also used, but that designation is less common than 'sodar'.)

The first sodars, which appeared in the early 1970s, emitted an acoustic pulse in a single vertically pointing beam as shown in [Figure 19](#). The sodar geometry shown, with the acoustic

Figure 19 Geometry for a monostatic sodar. An array of transducers projects a short burst of acoustic waves vertically in a beam. Turbulence-generated temperature inhomogeneities scatter sound back toward the transmitting transducers, which act as a directional receiver for the faint echoes received on the ground.

source and receiver collocated, is common and is known as a 'monostatic' sodar. (A less common geometry has the receiver separated horizontally from the transmitter and is called a 'bistatic' sodar.) When the upward-going pulse encounters temperature inhomogeneities produced by turbulence, faint scattered waves are created within the air itself. With monostatic sodar, the part of the acoustic wave scattered back toward the ground, the echo, is detected using the same transducers that produced the probe beam.

Early sodars were used primarily as instruments for detecting turbulence. The time delay between the emitted pulse and its echo determined the height of the turbulence (one-half the time delay times the average speed of sound), while the strength of the echo was a measure of the turbulence intensity. The evolving structure of the atmospheric boundary layer could be 'mapped' by plotting the delay time and echo strength on a vertically moving strip of paper. For example, the horizontal distance on the strip could be proportional to the time delay of the echo, and the darkness could be proportional to the intensity of the echo. With many repeated pulses, the evolution of the boundary layer could be followed visually. With its debut in the 1970s, the sodar immediately provided important insights into the spatial structure and temporal evolution of the atmospheric boundary layer. A typical sodar record is shown in [Figure 20](#). The figure has time moving from left to right and shows the evolution of boundary layer structures over a typical diurnal period. The vertical scale in the figure is 0–500 m, and the thin white vertical streaks are hour markers. Panel (a) shows a typical daytime record of thermal plumes carried through the vertical sodar beam. Panel (b) shows the turbulent boundary layer descending in the late afternoon and evening as solar heating of the ground diminishes. The undulations in the latter part of the record indicate the onset of IGW. Panel (c) shows fully developed IGW activity after midnight.

In addition to visual displays of boundary layer structure and dynamics, modern sodars can provide quantitative measures of wind and temperature. The so-called 'Doppler sodar,' for example, which uses two slant beams in addition to the usual vertically pointing beam, can map vector wind velocity versus height. A typical geometry would have a vertical beam, together with slant beams pointing north and east, respectively, at 70–75° above horizontal (15–20° off vertical). Using the Doppler shift in the echoes (upshift for winds moving toward the receiver and downshift for winds moving away from the receiver), the three vector components of wind velocity (up–down, east–west, and north–south) can be measured as a function of height. Such advances as the Doppler sodar are due, in large part, to the vast increase during the past 30 years in the computing power available with small computers. In addition to providing greatly increased signal processing power, small, powerful computers have also made remote sensing instruments like the Doppler sodar sufficiently 'user friendly' that nonexperts can operate them successfully.

A second important advance in acoustic remote sensing is the 'radio acoustic sounding system,' or RASS, which can provide accurate temperature profiles as a function of height. A RASS uses a single vertically pointing sodar beam together with two radar beams that converge in the air column over the sodar. The radar is used in a bistatic geometry with the transmitter on one side of the sodar and the receiver on

Figure 20 Record from a sodar taken over a diurnal cycle. The vertical scale is 0–500 m, and time increases from left to right. The vertical white lines are hour markers. (a) Unstable daytime boundary layer with thermal plumes generated by solar heating of the ground. (b) Decreasing daytime boundary layer followed by a growing stable nocturnal boundary layer showing evidence of initial gravity wave activity. the other side. Using coherent radar backscatter from the upward-going acoustic beam, the RASS measures the speed of the acoustic beam as it propagates upward. After making corrections for the (small) vertical component of wind velocity, one can estimate the adiabatic sound speed (a function of temperature only) as a function of height, which then yields the temperature as a function of height. Extensive comparisons between RASS measurements and *in*

situ measurements have shown that a RASS provides reliable estimates of temperature at heights from a few hundred meters to up to several kilometers.

Synopsis

Atmospheric tides are planetary-scale wave motions in the neutral atmosphere with periods defined by Earth's rotation rate. They are among the most striking dynamical features in the mesosphere and thermosphere, and are known to redistribute ionospheric plasma through dynamo processes. This article reviews the salient features of the tides from theoretical and observational perspectives, including the recent discovery that atmospheric tides connect planetary-scale weather patterns with the 'space weather' of the ionosphere-thermosphere.

Introduction

Atmospheric tides are ubiquitous features of the Earth's atmosphere. They are the persistent global oscillations that are observed in all types of atmospheric fields, including wind, temperature, pressure, density, and geopotential height. Tidal oscillations have periods that are some integer fraction of a solar or lunar day. The solar diurnal and semidiurnal tides have 24 and 12 h periods, respectively. The lunar diurnal tidal period is about 24.8 h, while the lunar semidiurnal period is 12.4 h. Scientists often use a shorthand notation to represent solar and lunar tides. S1 and S2 refer respectively to the solar diurnal and semidiurnal tides. Their lunar counterparts are M1 and M2.

Atmospheric tides have been studied for many years, since they are evident in both surface pressure and magnetic observations that date back to the early part of the twentieth century. **Figure 1** illustrates a time series of surface pressure measurements made at Batavia (now known as Jakarta, Indonesia) during the first 5 days of January in 1925. The dominant feature of this time series provides evidence of the solar semidiurnal atmospheric tide. Specifically, there is a 1 to 2-hPa deviation from the average pressure of about 1011 hPa that occurs regularly at 12 h intervals. This semidiurnal variation is modulated by other variations, but the former is such a persistent oscillation that the semidiurnal tide is also the dominant oscillation in monthly, yearly, and even multiyear averages of daily surface pressure measurements made at Batavia.

Atmospheric tides are further characterized by their sources. The Moon's gravity forces the lunar atmospheric tide, while solar

atmospheric tides can be excited in several ways, including the absorption of solar radiation, large-scale latent heat release associated with deep convective clouds in the troposphere, the gravitational pull of the Sun, and as secondary waves due to nonlinear wave-wave interactions. The restoring force that acts on atmospheric tides is gravity, so tides are a special class of buoyancy or gravity waves. Unlike high-frequency gravity waves, tides are affected by the Earth's rotation and sphericity because of their comparatively large periodicities and horizontal scales. Solar atmospheric tides are generally larger than lunar tides and dominate the tidal motions in the middle and upper atmosphere, that is, the stratosphere, mesosphere, and thermosphere. **Movie 1** illustrates the combined diurnal and semidiurnal tidal motions caused by solar atmospheric tides in the lower thermosphere. Temperature and wind speeds can vary by more than 60 K and $>100 \text{ m s}^{-1}$ within a few hours.

The general mathematical expression for a tidal oscillation is given by **eqn [1]**, where A is the magnitude of the variation in some atmospheric field, σ is its frequency, t is universal time, λ is longitude, and $s \geq 0$ is the zonal wavenumber (the number of wave crests that occur along a latitude circle). The $(s\lambda - \sigma t)$ form of **eqn [1]** is chosen so that the sign of σ is indicative of the zonal direction of propagation: $\sigma > 0$ corresponds to eastward propagating waves and $\sigma < 0$ to westward propagating waves. φ is the so-called tidal phase. A crest of the wave occurs when **eqn [2]** is satisfied.

$$A \cos(s\lambda - \sigma t - \varphi) \quad [1]$$

$$\varphi = s\lambda - \sigma t \quad [2]$$

The horizontal phase speed of the tide, c_{ph} , is defined by differentiating **eqn [2]** (**eqns [3] and [4]**).

$$sd\lambda - \sigma dt = 0 \quad [3]$$

$$c_{ph} \equiv \frac{d\lambda}{dt} = \frac{\sigma}{s} \quad [4]$$

For solar tides, the m th harmonic frequency is $\sigma_m = m\sigma_1$, where m is a positive or negative integer and $\sigma_1 = (2\pi/24) \text{ h}^{-1}$. Rewriting the mathematical expression for a tide in terms of LT (hours), $t_L = t + \lambda/\sigma_1$, results in a mathematical expression of the form of **eqn [5]**.

Figure 1 Surface pressure (hPa) at Batavia (Jakarta, Indonesia) against time during the first 5 days of January 1925.

$$A \cos((s + m)\lambda - \sigma_m t_L - \varphi) \quad [5]$$

For the subset of atmospheric tides known as migrating solar tides, $s = -m$ (with $m < 0$) and eqn [5] reduces to eqn [6].

$$A \cos(|m|\sigma_1 t_L - \varphi) \quad [6]$$

Thus, migrating solar tides have the same local time variation at all longitudes. If $m = -1$ and $s = 1$, the tide is diurnal and moves or migrates westward in longitude with the apparent motion of the Sun from the perspective of a ground-based observer. Further, $c_{ph} = -(2\pi/24) \text{ h}^{-1}$. Similarly, if $m = -2$ and $s = 2$, then the wave is a migrating semidiurnal tide. The remaining set of global-scale waves with tidal periods that are not Sun-synchronous are known as nonmigrating tides. Nonmigrating tides may be viewed as waves that propagate to the west more rapidly or slowly than the Sun, or that propagate eastward, or that are standing. Migrating and nonmigrating solar tides are often identified by using a letter/number code that indicates frequency, propagation direction, and zonal wavenumber: DWs or DEs is a westward or eastward propagating diurnal tide, respectively, with positive zonal wavenumber s . For semidiurnal tides, D is replaced by S, and D0, S0 are standing diurnal and semidiurnal tides, respectively. With this nomenclature, the migrating diurnal (semidiurnal) tide is DW1 (SW2) and DE3, for example, is an eastward propagating diurnal tide of zonal wavenumber 3.

All tides contain components that propagate in the vertical direction z . The effects of upward-propagating tidal components are particularly important because these waves grow in amplitude $\sim \exp(z/2H)$ with scale height $H (=k_B T/Mg)$ where k_B is the Boltzmann constant, T is temperature, M is the mean molecular mass, and g is Earth's gravity acceleration) as they conserve energy in an atmosphere whose density decreases with increasing altitude. Thus, tides with insignificant amplitudes in their lower atmospheric regions of excitation often affect the upper atmosphere profoundly because they introduce large atmospheric variations with local time and because they may dissipate and deposit their energy and momentum therein.

Classical Tidal Theory

Classical tidal theory treats the tides as perturbations on a basic state with neither mean-flow nor horizontal temperature gradients in an inviscid atmosphere. It provides a reasonable description of atmospheric tides in the lower and middle atmosphere, including the mesosphere and is therefore quite useful to demonstrate important tidal characteristics. As described in detail by Chapman and Lindzen (1970), the linearized primitive equations (Dynamical Meteorology: Primitive Equations) for wave motions described by eqn [1] and given (s, σ) can be reduced to a single equation for, for example, geopotential. The resulting equation is separable in its latitude and altitude dependence. The latitudinal part is described by Laplace's tidal equation and solved by a complete orthogonal set of eigenfunctions (called Hough modes) and eigenvalues or separation constants (called equivalent depths).

Each Hough mode $\Theta_n^{s,\sigma}$ is a series of associated Legendre polynomials with $|n| \geq s$ being the so-called meridional index

because it provides information on the number of latitudinal nodes and symmetry characteristics. It is quite common to refer to a specific Hough mode as the Θ_n^s mode or simply the (s, n) mode and to provide the frequency information externally. The equivalent depth $h_n^{s,\sigma}$ determines the vertical structure of each Hough mode because it is linked to the vertical wavelength λ_z (eqn [7]),

$$\lambda_{z,n}^{s,\sigma} = \frac{2\pi H}{\sqrt{\left(\kappa H + \frac{dH}{dx}\right) \frac{h_n^{s,\sigma}}{H} - \frac{1}{4}}} \quad [7]$$

with scale height H , $\kappa = (\gamma - 1)/\gamma$ and adiabatic index $\gamma \approx 7/5$, and normalized height $x = z/H$. Equation [7] implies that equivalent depths must be positive but smaller than roughly 8 km for vertical wave propagation. Larger values or negative equivalent depths imply vertically trapped modes. Figure 2 illustrates Hough modes corresponding to the first two propagating and trapped modes of the migrating DW1 and nonmigrating DE3 tides, respectively. Diurnal propagating modes generally maximize at low to middle latitudes and trapped modes at middle to high latitudes.

Figure 2 (a) Hough modes for the migrating diurnal solar tide (DW1). The meridional index n is positive for propagating tides and negative for trapped tides. (b) Same as (a) but for the DE3 nonmigrating tide.

Symmetric Hough functions are mirror images about the equator and occur if $n + s$ is even (odd) for positive (negative) values of n . Antisymmetric modes change sign at the equator and occur if $n + s$ is odd (even) for positive (negative) n . Tidal variations δF in temperature, pressure, geopotential, density, and vertical wind as function of normalized height x , latitude ϑ , zonal wavenumber s , and frequency σ are described by eqn [8]

$$\delta F^{s,\sigma}(x, \vartheta) = \sum_n \delta F_n^{s,\sigma}(x) \Theta_n^{s,\sigma}(\vartheta) \quad [8]$$

Zonal (u) and meridional (v) wind variations are described by eqns [9] and [10],

$$\delta u^{s,\sigma}(x, \vartheta) = \sum_n \delta u_n^{s,\sigma}(x) U_n^{s,\sigma}(\vartheta) \quad [9]$$

$$\delta v^{s,\sigma}(x, \vartheta) = \sum_n \delta v_n^{s,\sigma}(x) V_n^{s,\sigma}(\vartheta) \quad [10]$$

with the wind expansion functions shown in Figure 3 (eqns [11] and [12])

Figure 3 (a) Wind expansion functions for the migrating diurnal solar tide (DW1). The first two propagating modes are shown. (b) Same as (a) but for the DE3 nonmigrating tide.

$$U_n^{s,\sigma}(\vartheta) = \frac{1}{(f^2 - \sin^2 \vartheta)} \left[\frac{s}{\cos \vartheta} + \frac{\sin \vartheta}{f} \frac{d}{d\vartheta} \right] \Theta_n^{s,\sigma}(\vartheta) \quad [11]$$

$$V_n^{s,\sigma}(\vartheta) = \frac{1}{(f^2 - \sin^2 \vartheta)} \left[\frac{s \tan \vartheta}{f} + \frac{d}{d\vartheta} \right] \Theta_n^{s,\sigma}(\vartheta) \quad [12]$$

with $f = \sigma/(2\Omega)$ and Earth's angular velocity Ω . The zonal wind expansion functions $U_n^{s,\sigma}$ have the same symmetry as the corresponding Hough modes. $V_n^{s,\sigma}$ on the other hand are symmetric (antisymmetric) when the corresponding Hough modes are antisymmetric (symmetric).

The classical tidal theory approximates the tidal motions in the lower and middle atmosphere reasonably well, including the mesosphere. Classical methods of computing tides, however, do not work when mean zonal winds or dissipation are included, because the mathematical solutions become inseparable in the latitudinal and vertical coordinates. Hough modes are no longer eigenfunctions of the system and numerical solutions are needed. This is particularly important in the thermosphere where the tides undergo a substantial change in their modal structure when molecular dissipation becomes important. This transition height occurs approximately where the dissipative time scale equals the scale height divided by the vertical group velocity. Amplitudes and phases relax to approximately constant values in the thermosphere and the damping significantly broadens the horizontal structure. It should also be noted that the time constants of eddy and molecular diffusion are proportional to the square of λ_z . Short vertical wavelength tides or modes therefore dissipate more rapidly and cannot propagate into the thermosphere at all.

Migrating Solar Tides

The absorption of radiation by a longitudinally invariant atmosphere is the primary source of migrating solar tides. Owing to the rotation of the Earth, this absorption is periodic in time from the perspective of the ground-based observer. The resultant heating gives rise to migrating tidal oscillations. Solar radiation is absorbed throughout the Earth's atmosphere, thereby exciting migrating solar tides at almost all altitudes. Atomic oxygen, which is the most abundant atmospheric constituent at altitudes about 150 km above the Earth's surface, absorbs the shortest-wavelength solar radiation, known as the extreme ultraviolet. Increasingly longer wavelengths are absorbed as the solar radiation approaches the Earth's surface. Molecular oxygen (O_2) absorbs the far-ultraviolet radiation (100–200 nm) at altitudes near about 100–150 km, and ozone (O_3) absorbs the 200 to 300-nm solar ultraviolet radiation at middle atmospheric altitudes between about 30 and 70 km. Solar infrared radiation may be absorbed by water vapor (H_2O) in the lowest part of the atmosphere.

Even though there is little, if any, tidal forcing due to solar heating in the upper mesosphere (~ 80 – 100 km), measurements of winds and temperatures exhibit strong tidal signatures in this region. Figure 4 illustrates an example of the magnitude of the mean winds and the tidal oscillations over Adelaide, Australia, at these altitudes. The data points represent the eastward winds that were measured with the Buckland Park radar during 2 days in August 1994. The dashed curves

Figure 4 Eastward winds (m s^{-1}) over Adelaide, Australia, against local time (h) on 8–9 August 1994 at 98 km (top), 94 km (middle), and 90 km (bottom). Data points are radar measurements and dashed curves are model predictions that include the migrating diurnal and semidiurnal tidal components. Professor R.A. Vincent provided the Adelaide radar data.

illustrate global-scale wave model (GSWM) tidal predictions for August at the location of Adelaide. While the GSWM differs from the measurements in detail, the model captures the salient features of the observed winds, particularly on 8 August. Differences may be attributable to small-scale waves that are not included in GSWM or to sources of day-to-day tidal variability that are also omitted.

The GSWM predictions include mean winds ($17\text{--}18 \text{ m s}^{-1}$) and both migrating diurnal and semidiurnal components. Notably, the migrating diurnal amplitudes ($20\text{--}30 \text{ m s}^{-1}$) are larger than the mean winds. The GSWM diurnal tidal amplitudes are at least a factor of 2 larger than the semidiurnal amplitudes ($8\text{--}15 \text{ m s}^{-1}$) and the phases of both components shift to earlier times with increasing altitude between 90 and 98 km. This behavior, which is known as downward phase progression, is indicative of upward-propagating wave energy. There are clear signatures of downward phase progression in the GSWM predictions in **Figure 4**. That is, the wind predictions are most westward near 15.00 h at 98 km and there are similar features at progressively later times and progressively lower altitudes. The vertical wavelength of the migrating diurnal tide over Adelaide is much shorter than that of the migrating semidiurnal tide, so the phase of the former progresses far more rapidly than the phase of the latter and their

combined effects result in a pattern of wave maxima and minima that evolves between altitudes.

The migrating diurnal tide below the mesopause (i.e., the region between the mesosphere and thermosphere) originates primarily in the troposphere. Although tropospheric semidiurnal forcing is nonnegligible, there is comparatively more semidiurnal forcing in the middle atmosphere. Thus, the diurnal tidal growth occurs over a deeper altitude region than the semidiurnal growth and it is reasonable to anticipate a diurnal amplitude that is larger than the semidiurnal amplitude in the upper mesosphere. The aggregate characteristics of the mean winds and tides that are illustrated in **Figure 4** support the claim that upward-propagating migrating tides govern the large-scale dynamics of the upper mesosphere.

Migrating tides exhibit somewhat complicated behavior in that the latitudinal structure of the horizontal wind oscillations is dramatically different from the temperature, pressure, or vertical velocity structure. For example, the upward-propagating migrating diurnal tide DW1 is characterized by a primary temperature amplitude maximum over the Equator with secondary maxima near $\pm 30^\circ$. The horizontal wind amplitudes (**Movie 2**) exhibit minima over the Equator and nearly symmetric amplitude peaks at low to middle latitudes ($\pm(20\text{--}30^\circ)$). While ground-based observations provide an important perspective on the local behavior of waves with tidal frequencies, it is impossible to decipher global structures from local structures without conducting correlative analysis of measurements made at multiple locations over a broad range of latitudes. Further, in order to distinguish migrating from nonmigrating tidal components, it is necessary to have a longitudinal distribution of measurements.

The upward-propagating migrating tides dissipate in the lower thermosphere and their contribution to upper thermosphere variability is comparatively small. However, the longitudinally invariant absorption of solar far and extreme ultraviolet radiation efficiently forces a large *in situ* component of the migrating tides that dramatically changes the temperature, density, and wind structure in the upper thermosphere. **Figure 5** illustrates its magnitude based on the output from the NRLMSISE-00 (i.e., the 2000 version of the Naval Research Laboratory Mass Spectrometer Incoherent Scatter Radar Extended) empirical model. Local time mass density variations at 12:00 Universal Time are on the order of a factor of 3 when the tides (diurnal, semidiurnal, terdiurnal) are included (left panel) but almost nonexistent when the

Figure 5 Global distribution of neutral mass density at 12:00 Universal Time and 400 km altitude on 21 September 2010 with (left) and without (right) thermospheric tides. Data shown are from the NRLMSISE-00 model and do not include nonmigrating tides.

tides are excluded (right panel). The largest tidal signal in [Figure 5](#) (left panel) comes from the migrating diurnal tide DW1. It maximizes at the equator (latitude of the subsolar point during equinoxes) and decreases toward higher latitudes along with the noontime solar angle, as expected for an *in situ* forced tide. NRLMSISE-00 does not include nonmigrating tides. Recent diagnostics of upper thermosphere neutral density observations from the CHALLENGING Minisatellite Payload (CHAMP) satellite indicate that nonmigrating tides induce an additional longitudinal variability on the order of 30–50%, mostly due to upward-propagating tides from the troposphere. An accurate description of migrating and nonmigrating diurnal density variations is especially important for predicting low perigee satellite trajectories because atmospheric drag is the dominant error source in operational models.

Nonmigrating Tides

Near the surface of the Earth the strong longitudinal differences in topography, land–sea contrast, and surface interactions produce zonal (i.e., along a latitude circle in the east–west direction) variations in the local time behavior of the atmosphere and thus excite nonmigrating tides. A good example is latent heat release due to condensation in large-scale deep convective systems in the tropical troposphere. [Figure 6](#) illustrates the latitude–longitude distributions of the diurnal (left) and semidiurnal (right) latent heat release amplitudes during the month of September derived from satellite-borne convective rainfall measurements. Both components maximize at low latitudes where the absorption of solar radiation (evaporation) is greatest. Their longitudinal structure reflects the areas of largest deep convective activity in the tropical troposphere: one peak over Africa, followed by two peaks over Indonesia and the western Pacific and a fourth over South and Central America.

Through Fourier analysis the longitude variations depicted in [Figure 6](#) may be decomposed into a series of wave components with different zonal wavenumbers s . Each of the resultant nonmigrating tidal components possesses different vertical propagation characteristics that depend on its sensitivity to the prevailing winds and its vertical wavelength. Good examples are the DW5 and DE3 components. Both are efficiently forced by latent heat release but DW5 dissipates at higher altitudes

due to its short vertical wavelength. DE3 on the other hand has a long vertical wavelength and propagates up into the lower thermosphere where its magnitude rivals the radiatively forced migrating diurnal tide ([Movie 2](#)).

It is difficult to track vertical tidal propagation into the upper atmosphere such as that depicted in [Movie 2](#) because the distribution of ground-based observations is spatially limited. This is particularly true for altitudes between about 30 and 180 km above the Earth's surface, which encompass the region where the upward-propagating waves attain large amplitudes and subsequently dissipate. It is generally impossible to distinguish migrating from nonmigrating tides in the analysis of ground-based remote-sensing measurements from a single site made at these altitudes. During the 1990s remote sensing from the Upper Atmosphere Research Satellite (UARS) considerably ameliorated this problem. Further progress came from the Thermosphere Ionosphere Mesosphere Energetics and Dynamics (TIMED) satellite that was launched in 2001 because it allowed for the first time to observe the global tidal spectrum in various parameters over a range of mesosphere and lower thermosphere altitudes. The data utilized to construct [Movies 1–4](#) consist of wind measurements made by the TIMED Doppler Interferometer (TIDI) and temperature measurements made by the Sounding the Atmosphere using Broadband Emission Radiometry instrument that are extended toward the poles and into the lower atmosphere and upper thermosphere using an empirical tidal model.

[Movies 3 and 4](#) illustrate the latitude–longitude distribution of the diurnal and semidiurnal tides at 100 km for the month of September, averaged over 7 years from 2002 to 2008. The superposition of these movies is shown in [Movie 1](#). The diurnal tide with amplitudes as large as 28 K and 42 m s^{-1} , respectively, mainly consists of the migrating component DW1 and the nonmigrating DE3 tide, with some contributions from the DE2, D0, and DW2 components. The migrating tide is observed as a zonally symmetric oscillation because the movie is animated in LT (compare [eqn \[5\]](#)) and the DE3 as a 4-peaked longitudinal variation for the same reason. The semidiurnal tidal field is more symmetric than the diurnal one with amplitudes of 17 K and 36 m s^{-1} , respectively. Spectral analysis of these particular data reveals that the longitudinal structure is dominated by the migrating tide SW2, with contributions from the SW3, SW1, and SE2 nonmigrating tides.

Complementary numerical modeling studies suggest that the diurnal and semidiurnal nonmigrating tides are

generated in the lower levels of the atmosphere, either by latent heat release (DE3, DE2, SE2) and/or as secondary waves by the nonlinear interaction between stationary planetary waves and the migrating tides (DW2, D0, SW1, SW3). An example from the 'Whole Atmosphere Model' (WAM) is shown in [Figure 7](#). WAM is a general circulation model of the neutral atmosphere built on an existing operational Global Forecast Model used by the U.S. National Weather Service. It includes realistic topography, latent heating associated with tropospheric convection and nonlinear processes, and the model domain extends well into the dissipative thermosphere to a top level of about 600 km. The WAM temperature and zonal wind components associated with the DE3 tide exhibit maxima centered around the equator that can also be discerned in the TIMED satellite measurements shown in [Movie 2](#).

Lunar Tides

Lunar atmospheric tides are only about 5–10% as large as solar tides, but they have clearly detectable effects. The lunar tidal pressure at the ground maximizes at low latitudes, with an average amplitude of about 7 Pa. The corresponding wind amplitude at the Equator is about 0.03 m s^{-1} . The wind amplitude increases with altitude up to about 110 km, where it reaches an amplitude on the order 10 m s^{-1} .

Unlike the solar tides, the lunar atmospheric tides are entirely driven by gravitational forces, as illustrated schematically in [Figure 8](#). Because the lunar gravitational acceleration decreases as the inverse square of the distance from the center of the Moon, this acceleration is not exactly uniform near the Earth, so that atmospheric air parcels at various locations around the Earth experience slightly different lunar accelerations from those of the Earth as a whole. Air parcels in the hemisphere most distant from the Moon are accelerated toward the Moon less strongly than is the Earth, in effect creating a relative acceleration away from the Moon for these air parcels, in the Earth's reference frame. Conversely, air parcels in the moonward hemisphere of the Earth experience a relative acceleration toward the Moon. In each hemisphere, parcels to the west of a line passing through the centers of the Earth and Moon experience an eastward

component of acceleration, while those to the east of this line experience a westward acceleration. As the Earth rotates, during a lunar day (24.8412 h on the average) an air parcel at the Equator successively passes twice through regions of westward and eastward acceleration, comprising two lunar semidiurnal cycles of period 12.4206 h. When the Moon is north or south of the Earth's Equator, an additional diurnal lunar cycle (period 24.8412 h) of acceleration exists at nonequatorial latitudes. There is also a monthly periodicity to the forcing as the Moon cycles between the Northern and Southern Hemispheres of the Earth. Both this cycling and the ellipticity of the Moon's orbit create amplitude and frequency modulation of the lunar semidiurnal and diurnal forcings that can be expressed as combinations of multiple closely spaced periods. The dominant lunar period, representing the average lunar semidiurnal tide, is referred to as the M2 tide, with a 12.4206 h period.

In addition to the direct forcing of lunar gravity on the atmosphere, lunar atmospheric tides are indirectly forced by

Figure 8 Schematics of lunar tidal forcing in the reference frames of the Moon (top) and the Earth (bottom). The Earth is viewed from above the North Pole and the Moon (not shown) is to the right.

Figure 9 Contours of M2 lunar semidiurnal surface pressure amplitude (dPa) against longitude and latitude for the month of December. Dr F. Vial collaborated with Professor J.M. Forbes to produce the model results.

lunar gravity through deformation of the Earth's surface due to ocean and Earth tides. The vertical velocity associated with this deformation significantly affects the atmospheric tide, and the modulation of terrestrial gravity by the deformation of the Earth's mass distribution also has an effect. These indirect forcing effects can be determined accurately from measurements of ocean and Earth tides, so that the total lunar tidal forcing is well known. This is beneficial for testing theoretical models of tidal propagation and dissipation in the atmosphere. The indirect forcing effects, because they depend on land–sea differences, are a function not only of apparent lunar position but also of geographical location, and generate nonmigrating tides in addition to the primary migrating lunar tides.

It is possible to develop a model of the M2 lunar semidiurnal atmospheric tide that produces results that agree very satisfactorily with the observed tide in the surface pressure. Such a model must account for all direct and indirect lunar forcing effects, and include realistic atmospheric wind and temperature structures. **Figure 9** illustrates prototypical M2 model results and shows how the lunar tidal amplitude varies with latitude and longitude over the Earth for atmospheric conditions representing the month of December. The largest amplitudes in this month are at low latitudes, but they vary from less than 4 Pa (40 dPa) on the east coast of South America to more than 12 Pa over the mid-Pacific. A secondary maximum appears over the northern Atlantic. On the average, the amplitude of the M2 tide at low latitudes is larger around the solstices than at the equinoxes, by roughly 50%. Some of the largest geophysical effects of atmospheric lunar tides appear in the low-latitude ionosphere, as discussed in the next section.

Tides in the Ionosphere

Tides in the ionosphere are spatiotemporal variations in electric fields, currents, and plasma density in the ionosphere primarily due to dynamo effects generated by solar and lunar tidal motions in the neutral background atmosphere. Tidal winds in the low and middle latitude E-region move the partially ionized plasma through the Earth's magnetic field while the electrons with their high gyro frequency/collision frequency ratio remain fixed to the magnetic field lines. An electromotive force is thus created with ensuing electric currents and polarization electric fields.

During the daytime, when the conductivity is large owing to ionizing solar radiation, the electric currents, commonly labeled S_q for 'solar quiet,' flow approximately counter

Figure 10 The northward component of magnetic perturbation (in nanoteslas) at Huancayo, Peru, against local time (h) on the 5th and 12th days following new moon reveals evidence of lunar tidal effects on top of the larger solar tidal effects.

clockwise in the Northern Hemisphere and clockwise in the Southern Hemisphere with vortex foci at roughly $\pm 30^\circ$ magnetic latitude. A particularly strong eastward current, called equatorial electrojet, exists along the geomagnetic equator because the effective ionospheric conductivity is unusually high in the lower ionosphere at latitudes where the geomagnetic field is nearly horizontal. The S_q currents produce perturbations in the Earth's magnetic field that are readily measured at the ground. **Figure 10** shows the northward component of the magnetic perturbation at Huancayo, Peru, for two phases of the lunar tide: 5 and 12 days following new moon. These represent average conditions in 1957–58 for the months of November–February, when the lunar tide in the ionosphere is generally largest. The larger solar diurnal and semidiurnal tides produce a northward perturbation that maximizes daily at around 11.00 LT. On day 5, the lunar tide enhances the magnetic perturbation at 11.00 LT, but reduces it in the late afternoon. On day 12 the phase of the lunar tide and its effects are reversed from those on day 5. Clear lunar effects in the low-latitude ionospheric electron density are also found.

The E-region dynamo polarization electric fields are further transmitted along magnetic field lines into the overlying F-region where they drive vertical ($\sim 20 \text{ m s}^{-1}$) and zonal ($\sim 100 \text{ m s}^{-1}$) plasma drifts, which influence many important ionospheric processes. For example, vertical $\mathbf{E} \times \mathbf{B}$ drifts drive the plasma fountain which results in dense bands of plasma

centered near $\pm 15\text{--}20^\circ$ magnetic latitude. This so-called equatorial ionization anomaly can be seen in the top center panel in [Figure 11](#), as the two bluish bands north and south of the magnetic equator. The two ionization crests are predominantly the result of migrating solar tidal winds in the E-region while the apparent longitudinal modulation on top, indicated by brighter colors, is the result of nonmigrating tides excited in the troposphere by latent heat release in deep convective clouds.

The realization that nonmigrating tides due to tropospheric weather impact the F-region ionosphere, and as such couple these atmospheric layers that are 400 km apart, is a relatively new discovery that was made around the year 2005 due to new satellite observations and progress in numerical modeling. [Figure 11](#) summarizes these observations that are all displayed for a constant LT, and sketches the cause-and-effect chain of meteorological impacts on the IT system. The most striking pattern is a 4-peaked ‘wave-4’ longitudinal modulation that is apparent in deep convective cloud occurrence (observed by weather satellites, also compare [Figure 6](#)), E-region zonal winds (observed by TIMED, also compare [Movie 1](#)), thermospheric constituents (observed by the SNOE in equatorial nitric oxide density), electron density (observed by the COSMIC/Formosat-3), ion density (observed by IMAGE spacecraft in the far-

ultraviolet), and neutral mass density (observed by CHAMP). The ‘wave-4’ corresponds to the DE3 nonmigrating tide with some contribution from the SE2, because this is how these components are observed in a LT frame ([eqn \[5\]](#)). [Movie 2](#) and [Figure 6](#) show that the DE3 can achieve zonal wind amplitudes on the order of tens of m s^{-1} in the low latitude E-region. It thus efficiently modulates the E-region dynamo electric fields, resulting in the pronounced ‘wave-4’ F-region plasma density variations. All these observations and corresponding model simulations imply that tropospheric weather is an important contributor to the ‘space weather’ of the geomagnetically quiescent ionosphere, even for solar maximum conditions, and capable to change, for example, electron density by a factor of three within a few thousand kilometers.

Longitudinal variations in the ionospheric plasma due to nonmigrating tides do not always occur as a ‘wave-4’. The ‘wave-4’ dominates from March to October but changes to a 3-peaked ‘wave-3’ from November to February when observed at a fixed LT ([Figure 12](#)). This is mainly due to the seasonal variation of the diurnal nonmigrating tides in the E-region as depicted in [Figure 13](#). The DE3 dominates from March to October but it is exceeded by another component, the DE2 (observed as a ‘wave-3’) during Northern Hemisphere winter.

Figure 11 Meteorological impacts on the ionosphere–thermosphere due to nonmigrating tides as observed by different satellites. The ‘wave-4’ like latent heat release pattern in the troposphere is found throughout the ionosphere–thermosphere system in various neutral and ion parameters. Dr C.H. Lin provided the Constellation Observing System for Meteorology, Ionosphere & Climate (COSMIC) figure, which is adapted with permission from Lin, C.H., et al., 2007. Plausible effect of atmospheric tides on the equatorial ionosphere observed by the FORMOSAT-3/COSMIC: three-dimensional electron density structures. *Geophysical Research Letters* 34, L11112. doi:10.1029/2007GL029265. Bruinsma provided the CHAMP neutral density data. The Student Nitric Oxide Explorer (SNOE) nitric oxide figure is adapted with permission from Oberheide, J., Forbes, J.M., 2008. Thermospheric nitric oxide variability induced by nonmigrating tides. *Geophysical Research Letters* 35, L16814. doi:10.1029/2008GL034825. Deep tropical cloud data are from the International Satellite Cloud Climatology Project (ISCCP).

Figure 12 Seasonal variation of normalized total electron content from TOPEX/Poseidon observations for low (upper row) and high (lower row) solar flux conditions. Professor L. Scherliess provided these figures, which are adapted with permission from Scherliess, L., Thompson, D.C., Schunk, R.W., 2008. Longitudinal variability of low-latitude total electron content: tidal influences. *Journal of Geophysical Research* 113, A01311. doi:10.1029/2007JA012480.

Figure 13 Seasonal variation of the DE2 and DE3 zonal winds at the equator and 105 km as observed by the TIDI/TIMED instrument. The numbers in parentheses indicate the zonal wavenumbers when observed in a LT frame.

The leading role of E-region dynamo modulation in coupling tidal dynamics into the ionosphere is undisputed but there is growing evidence that other processes may play an important role. While *in situ* F-region ion drag has no measureable effect on the neutral ‘wave-4’ in the upper

thermosphere, models on the other hand suggest that tidal variations in thermospheric $[O]/[N_2]$ and meridional winds at F-region altitudes may add to the observed plasma variations, including effects from semidiurnal nonmigrating tides such as the SE2. Delineating and understanding these processes, including nonlinear wave-wave interactions and secondary wave generation, is one challenge for the time to come as tidal coupling from below constitutes a major energy term for the ionosphere–thermosphere system. It is particularly important since it is a prerequisite for improved space weather predictions including Global Positioning System outages due to ionospheric irregularities or biteouts.

Appendix A: Supplementary Data

Supplementary video related to this article can be found at <http://dx.doi.org/10.1016/B978-0-12-382225-3.00409-6>.

The following are the supplementary data related to this article:

Movie 1 Temperature (color) and wind variations (arrows) at 100 km during September due to diurnal and semidiurnal solar atmospheric tides. The movie is based on TIMED satellite observations and runs in local solar time (LT).

Movie 2 Zonal wind structure of the migrating diurnal tide (DW1, top) and the eastward propagating nonmigrating tide of zonal wavenumber 3 (DE3, bottom). The movie is based on TIMED satellite observations and empirical modeling and runs in universal time. The right column shows the vertical structure of the tides at 90° E longitude. Downward phase progression indicates tidal forcing from below. Thermospheric tides due to far and extreme ultraviolet absorption are not included.

Movie 3 Temperature (color) and wind variations (arrows) at 100 km during September due to diurnal solar atmospheric tides. The movie is based on TIMED satellite observations and runs in LT.

Movie 4 As **Movie 3** but for the semidiurnal tide.

Balanced Flow

ME McIntyre, University of Cambridge, Cambridge, UK

Synopsis

A balanced flow is one in which the three-dimensional velocity field is functionally related to the mass field, presumed hydrostatically related to the pressure field. Such a functional relation between the velocity and mass fields is called a balance relation, or filtering condition. The simplest but least accurate such relation is geostrophic balance. There are more accurate balance relations, of which the most accurate are fully nonlocal. That is, the velocity at a point depends on the mass field throughout the domain. There are ultimate limitations to accuracy, governed by the fuzziness of the slow quasimanifold.

Introduction

The concept of *balanced flow* is the counterpart, in atmosphere–ocean dynamics, to the well-known concept of nearly incompressible flow in classical aerodynamics. In aerodynamics, a key aspect of such flow – long recognized as central to understanding the behavior of subsonic aircraft – is that all the significant dynamical information is contained in the vorticity field. To that extent the flow has, in effect, fewer degrees of freedom than a fully general flow. We may think of it as being elastostatically balanced, in the sense that freely propagating sound waves can be neglected in the dynamics.

In atmosphere–ocean dynamics there is a corresponding statement with vorticity replaced by potential vorticity (PV), understood in a suitably generalized sense; see generalized PV field in the article **Dynamical Meteorology: Potential Vorticity**. For many cases of rotating, stably stratified fluid flow, with parameter values typical of the atmosphere and oceans, all the significant dynamical information is contained in the generalized PV field. One may invert this field at each instant to obtain the mass and velocity fields. The article on Potential Vorticity gives a more precise statement. All such flows may be characterized as balanced.

Again this means that the flow has, in effect, fewer degrees of freedom than a fully general flow. More precisely, balance and invertibility mean that not only sound waves but also freely propagating inertia–gravity waves can be neglected in, or filtered from, the dynamics. Thus balanced flows can be much simpler to understand than fully general flows, thanks to the relatively simple way in which the advective nonlinearity acts on the PV.

Cases of fluid flow describable as balanced come under headings such as Rossby waves, Rossby-wave breaking, vortex dynamics, vortical modes, vortical flow, vortex coherence, vortex resilience, eddy-transport barriers, blocking, cyclogenesis, baroclinic instability and barotropic instability (meaning the wavy shear instabilities), all of which are related to the fundamental Rossby-wave restoring mechanism or quasi-elasticity that exists whenever there are isentropic gradients of PV in the interior of the flow domain, or gradients of potential temperature on an upper or lower boundary. The concept of balanced flow is fundamental, also, to theories of wave–mean interaction and wave–vortex interaction, needed in order to understand, for instance, the gyroscopic pumping that drives global-scale stratospheric circulations and chemical transports

(§6 of **Dynamical Meteorology: Potential Vorticity**). In these theories the mean or vortical flow is usually considered to be balanced, regardless of the wave types involved. Indeed, the concept of balance enters, implicitly or explicitly, into almost any discussion of meteorologically interesting fluid phenomena; and balance versus imbalance is part of the conceptual foundation that underpins data analysis, data assimilation, and weather prediction.

The Elastic Pendulum

Balance has counterparts not only in aerodynamics but also in simple mechanical systems such as the elastic pendulum. This is a massive bob suspended from a pivot by a stiff elastic spring of negligible mass. Such a pendulum has slow, swinging modes of oscillation in which the relatively fast, compressional modes of the bob and spring are hardly excited: they can be neglected in the dynamics if the spring is stiff enough. The slow, swinging modes correspond to balanced flow, and the fast, compressional modes to sound and inertia–gravity waves. One may describe the swinging modes to a crude first approximation by making the spring strictly incompressible, i.e., by making its length strictly constant. There is a hierarchy of more accurate approximations that allow the spring to change its length in a quasi-static or elastostatic way, the spring being longest when the bob moves fastest and shortest when the bob is stationary.

In such a quasi-static description the length of the spring is functionally related to the speed of the bob. The functional relation holds at each instant t , i.e., it holds diagnostically. No derivatives or integrals with respect to t are involved, and values of t do not explicitly enter into the definition of the functional relation. The property of being diagnostic, in this sense, provides us with a useful mathematical and conceptual simplification.

Such approximations and their ultimate limitations can be studied mathematically via techniques ranging all the way from two-timing formalisms (method of multiple scales) and bounded-derivative theory to KAM (Kolmogorov–Arnol’d–Moser) theory and other dynamical-systems techniques; there is an enormous literature.

The error incurred in using the most accurate quasi-static descriptions becomes exponentially small as the fast–slow timescale separation increases. It may even be zero, or in some

circumstances small but inherently nonzero (corresponding to KAM tori breaking into thin chaotic layers, also called fractal layers or stochastic layers).

Balance Relations

In atmosphere–ocean dynamics the defining property of balance is that an analogous functional relation holds – diagnostic in precisely the same sense. The functional relation between bob speed and spring length is replaced by a functional relation between the fluid’s velocity and mass fields. More precisely, a flow is said to be balanced if the three-dimensional velocity field $\mathbf{u}(\mathbf{x}, t)$ satisfies a functional relation of the form $\mathbf{u}(\mathbf{x}, t) = \mathbf{u}^B$ where $\mathbf{u}^B$ depends only on the mass field or mass configuration, i.e., on the spatial distribution of mass throughout the fluid system, presumed to be hydrostatically related to the pressure field. (Knowledge of the mass field then implies knowledge of the pressure, temperature and potential temperature fields, given zero pressure at the top of the atmosphere.)

Such a functional relation $\mathbf{u}(\mathbf{x}, t) = \mathbf{u}^B$ between the velocity and mass fields is called a filtering or balance condition, or balance relation. It supplies just enough information to make the PV field invertible. The property of being diagnostic means that if one knows the mass field at some instant t , but knows nothing about its time dependence, nor the value of t itself, then the balance relation must nevertheless allow one to deduce the complete three-dimensional velocity field $\mathbf{u}$. It must allow the velocity field to be deduced from the mass field and from the mass field alone. (Such a diagnostic relation should not, however, be mistaken for a causal relation. To think that the mass or pressure field causes the velocity field is like thinking that the spring length causes the pendulum’s motion.)

To the extent that a balance relation holds it excludes, or filters, freely propagating sound waves and inertia–gravity waves from the repertoire of possible fluid motions. The system then has too few degrees of freedom to describe such waves. The reduction in degrees of freedom is sometimes expressed by saying that some degrees of freedom are slaved to others, or that the possible states of the dynamical system have been confined to a so-called slow manifold within phase space, having lower dimensionality than the full phase space in which it is embedded. In this language we say that, in particular, the velocity field is slaved to the mass field. A more careful statement would be that in the actual flow the velocity field evolves as if it were slaved to the mass field, to some useful approximation at least. This is like saying that the swinging motion of the pendulum evolves as if the bob speed were slaved to the spring length, to some useful approximation, even though there is no actual mechanical linkage between the two variables.

A standard example of a balance relation is the so-called *geostrophic relation*, which is simple to write and, for typical extratropical parameter values, qualitatively useful though quantitatively not very accurate:

$$\mathbf{u}(\mathbf{x}, t) = \frac{1}{f} \left(-\frac{\partial \Phi(\mathbf{x}, t)}{\partial y}, \frac{\partial \Phi(\mathbf{x}, t)}{\partial x}, 0 \right) \quad [1]$$

Here f is the Coriolis parameter, $\Phi(\mathbf{x}, t)$ is the geopotential height (approximately geometric altitude times gravitational

acceleration), and position $\mathbf{x}$ is specified using pressure altitude along with horizontal position x, y . Thus the horizontal spatial derivatives $\partial/\partial x$ and $\partial/\partial y$ are taken at constant pressure altitude rather than at constant geometric altitude. This qualifies as a balance relation because of the presumption that the hydrostatic relation also holds, as normally assumed when using pressure as the vertical coordinate. Knowing Φ on each constant-pressure (isobaric) surface is then equivalent to knowing the mass field. So eqn [1] is, as required, a diagnostic functional relation between the velocity field and the mass field. The vertical derivative of eqn [1] is the so-called thermal wind equation.

The horizontal coordinates x, y are orthogonal coordinates, and can be taken either as local curvilinear following the Earth’s geometry, or as local Cartesian in a tangent-plane approximation. If we also take $f = \text{constant}$, giving us the so-called f -plane approximation, then eqn [1] asserts not only that $\mathbf{u}$ is slaved to the mass field but also that it is two-dimensionally incompressible or nondivergent, with streamfunction $\Psi = \Phi/f$, so that

$$\mathbf{u}(\mathbf{x}, t) = \left(-\frac{\partial \Psi}{\partial y}, \frac{\partial \Psi}{\partial x}, 0 \right) \quad [2]$$

The geostrophic relation [1] – or relations, plural, if one prefers to think in components rather than vectors – can be motivated as an approximation to the horizontal momentum equation. The accuracy of that approximation depends on smallness of the Rossby number, or, more precisely, on being able to neglect relative particle (Lagrangian) accelerations against Coriolis accelerations, i.e., against f times either side of eqn [1]. The Rossby number Ro , measuring the advective contribution to the relative particle acceleration against the Coriolis acceleration, is usually of the same order as f^{-1} times a typical magnitude of the relative vertical vorticity $\partial v/\partial x - \partial u/\partial y$, the latter being equal to $\nabla_H^2 \Psi$ if eqn [2] holds. Here u and v are the horizontal velocity components corresponding to x and y , and ∇_H^2 is the horizontal Laplacian. Extratropical Rossby numbers have orders of magnitude typically $\sim 10^{-1}$ for synoptic-scale weather systems.

The geostrophic relation [1] was recognized long ago by weather observers as helpful in making sense of synoptic-scale surface pressure patterns, important for instance to ships threatened by cyclonic storms. The history is sometimes discussed under headings such as Buys Ballot’s law and cyclonic development theory. Buys Ballot’s law is a qualitative counterpart of eqn [1] with surface pressure in place of Φ , ‘wind in your back means low on your left’ – low surface pressure, that is, at sea level in the Northern Hemisphere.

Today’s concept of balance recognizes that, like the rigid-pendulum approximation, eqn [1] is merely the first in a hierarchy of more accurate balance relations. Next in the hierarchy is the relation first studied by Bert Bolin and Jule G. Charney in the 1950s, in connection with efforts to develop practical numerical weather prediction. The Bolin–Charney balance relation retains eqn [2] even if f varies with latitude, but redefines Ψ to satisfy

$$\nabla_H \cdot (f \nabla_H \Psi) = \nabla_H^2 \Phi + \nabla_H \cdot (\mathbf{u} \cdot \nabla_H \mathbf{u}) \quad [3]$$

where, as before, ∇_H is horizontally two-dimensional. Equation [3] is an approximation to the divergence equation, the

latter being the result of taking the horizontal divergence of the horizontal momentum equation. The relative particle acceleration is now retained. Its advective part gives rise to the last term of eqn [3] while the remaining, $\partial/\partial t$ part is annihilated when the horizontal divergence is taken, because of eqn [2]. It is only because there are no $\partial/\partial t$ terms that the relation [3], with [2], qualifies as a balance relation. In the special case of an isolated circular vortex on an f -plane, eqn [3] reduces to so-called gradient-wind balance, namely eqn [1] corrected to include the centrifugal force of the relative motion.

Again because of eqn [2], the right-hand side of eqn [3] can be rewritten using a Jacobian in u and v , as $\nabla_H^2 \Phi - 2\partial(u, v)/\partial(x, y)$, or equivalently using a Hessian in Ψ so that eqn [3] becomes

$$\nabla_H \cdot (f \nabla_H \Psi) = \nabla_H^2 \Phi - 2 \left\{ \frac{\partial^2 \Psi}{\partial x^2} \frac{\partial^2 \Psi}{\partial y^2} - \left(\frac{\partial^2 \Psi}{\partial x \partial y} \right)^2 \right\} \quad [4]$$

Regarded as an equation for Ψ when the mass field Φ is given, eqn [4] is of Monge–Ampère type, with an extensive mathematical theory. Iterative methods are needed to solve it numerically because of the nonlinear terms on the right. The problem of finding Ψ becomes ill-posed for certain mass fields Φ , adumbrating, for one thing, that there exist mass fields not even approximately balanceable by any velocity field.

A simple thought experiment to make this last point clear would be to pile up the whole of the Earth’s atmosphere into a narrow column above the North Pole, leaving a vacuum elsewhere. It is obvious that no velocity field $\mathbf{u}$ can be in balance with such a mass field. The free evolution at subsequent times, in any such thought experiment, would start with the column collapsing downward and outward and would involve sound and inertia–gravity waves of enormous amplitude. That is, it would involve gross imbalance as well as, almost certainly, violent wave-breaking and turbulence.

Balance relations are useful in practice only because naturally occurring mass fields, or at least smoothed versions of them are, by contrast, often balanceable to good approximation. In most such cases, eqn [4] with suitable boundary conditions is a well-posed nonlinear elliptic boundary-value problem in the flow domain, the primary exception being flows near the equator, where Rossby numbers are not small and eqn [4] may fail to be elliptic, as can be verified from the theory of Monge–Ampère equations. Again the failure of ellipticity adumbrates a physical reality (though not in a way that is quantitatively precise), namely the fact that balance is liable to break down spontaneously through ‘inertial’ and ‘symmetric’ instabilities near the equator, where f changes sign. There are other varieties of spontaneous imbalance, some only recently clarified. Again these are usually unimportant when Rossby numbers are small.

Balance relations still more accurate than eqn [4] can be defined if one is prepared to deal with more complicated sets of equations. The next relation in the hierarchy – to be referred to here as the generalized Bolin–Charney balance relation – is the first in the hierarchy to yield a nonvanishing vertical component of $\mathbf{u}$. It was implicit in the pioneering work of Charney published in 1962, in a famous paper entitled ‘Integration of the primitive and balance equations’. It starts with eqns [2] and

[4] but then adds to the resulting $\mathbf{u}$ field a horizontally irrotational, divergent correction field governed by another elliptic boundary-value problem in the flow domain, a generalization of the omega equation previously developed by Norman A. Phillips and others. The corrected $\mathbf{u}$ field is an asymptotically consistent improvement on eqn [1], for small Rossby number Ro , in the sense that it is one order more accurate in powers of Ro . The elliptic boundary-value problem is derived by taking $\partial/\partial t$ of eqn [4], then eliminating all the resulting time derivatives using the exact mass conservation and vorticity equations and the inverse Laplacian of the vorticity equation. The vorticity equation expresses $\nabla_H^2 (\partial \Psi / \partial t)$ in terms of diagnostically known, or knowable, quantities such as the corrected $\mathbf{u}$ field; so the inverse Laplacian is needed in order to eliminate $\partial \Psi / \partial t$ from $\partial/\partial t$ of eqn [4].

This process of eliminating all the time derivatives including others such as $\partial \Phi / \partial t$ has to be possible, in principle at least, if the end result is to be a balance relation. By definition, a balance relation may not contain any time derivatives. When the elimination is carried out explicitly, a rather complicated set of integro-differential equations results, containing Green’s function integrals whose details depend on the geometry of the flow domain. It may therefore be notationally and computationally more convenient to work with a set of equations from which $\partial \Psi / \partial t$, $\partial \Phi / \partial t$, etc., have not been eliminated, but have been allowed to remain as unknowns that can, in principle, be eliminated.

Then ‘ $\partial \Psi / \partial t$ ’, in scare-quotes, so to speak, must be regarded not as the rate of change of Ψ but, rather, as an auxiliary variable – better described as a diagnostic estimate of, as distinct from the actual, rate of change. Such a diagnostic estimate must be expected to differ, in general, from the actual rate of change of Ψ , for the reasons explained under *ultimate limitations* below. To avoid confusion over this point a special notation is sometimes used, such as Ψ_1 for a diagnostic estimate of $\partial \Psi / \partial t$ and Ψ_2 for $\partial^2 \Psi / \partial t^2$, and so on.

The general form of the functional dependence defining a balance relation, assuming a balanceable mass field represented by $\Phi(\mathbf{x}, t)$, can be written symbolically as

$$\mathbf{u}(\mathbf{x}, t) = \mathbf{u}^B(\mathbf{x}; \Phi(\cdot, t)) \quad [5]$$

where it is again emphasized that no derivatives or integrals with respect to t may appear. It must be possible, in principle at least, to eliminate them all. Time t enters solely via the second argument $\Phi(\cdot, t)$ of $\mathbf{u}^B$. The notation $\Phi(\cdot, t)$ follows mathematical convention and signifies nonlocal spatial dependence. In other words, the second argument of $\mathbf{u}^B$ is the whole *function*, Φ of $\mathbf{x}$, over the whole flow domain at the given instant t – not merely the *value* of Φ at the single value of $\mathbf{x}$ to which the left-hand side of eqn [5] refers. Such nonlocal functions are sometimes called functionals.

Even the geostrophic relation [1] is enough to illustrate the point, though it involves nothing more than the behavior of Φ in the immediate neighborhood of $\mathbf{x}$ – more precisely, it involves enough about that behavior to permit the evaluation of the two horizontal derivatives. The Bolin–Charney balance relations, generalized or not, are fully nonlocal, as is plain from the occurrence of elliptic partial differential operators like ∇_H^2 and, implicitly or explicitly, the associated Green’s function

integrals. To find $\mathbf{u}$ from Φ one has to solve elliptic partial differential equations in the flow domain, as already emphasized, implying for instance that the value of $\mathbf{u}$ at some position $\mathbf{x}$ will depend on values $\Phi(\mathbf{x}', t)$ at other positions $\mathbf{x}'$ well outside the neighborhood of $\mathbf{x}$.

The generalized Bolin–Charney balance relation is often accurate enough for practical purposes, such as observational data analysis and assimilation, and the initialization of the full dynamics for numerical weather prediction. Of fundamental interest, however, from a theoretical viewpoint, is the fact that the pattern of elimination of time derivatives can be extended systematically to higher derivatives, often resulting in balance relations that are still more accurate.

The ideas involved seem to have been first explored by Karl Hinkelman in the 1960s, in connection with the initialization problem in numerical weather prediction. They were later approached from another direction via the normal modes of the Laplace tidal equations, by Bennert Machenhauer, Ferdinand Baer, Joseph Tribbia and others. The history then went full circle, successively under headings such as nonlinear normal-mode initialization, bounded-derivative method, implicit normal-mode initialization, non-normal-mode initialization, and non-normal-mode filtering, of which the last four represent a rediscovery or further development of Hinkelman's ideas. The ideas were first applied to accurate PV inversion by Warwick A. Norton in the late 1980s. An ingenious numerical approach bypassing the explicit consideration of diagnostic estimates like $\Psi_1, \Psi_2, \dots$ or their normal-mode counterparts was developed by Álvaro Viúdez and David G. Dritschel in 2004.

The Ultimate Limitations

The most accurate balance relations can, in some circumstances, be far more accurate than values of parameters like the Rossby number Ro might ever suggest; and this accuracy extends over a far wider range of parameter values than could reasonably have been expected a priori – with Ro values of order unity, and even greater, in some cases. This astonishing fact – first discovered by Norton through numerical experiments on hemispherical shallow-water flows, for which $Ro = \infty$ at the equator – cannot be deduced by inspection or scaling analysis of the momentum equation or other forms of the equations of motion. It involves great mathematical subtlety, and full understanding has yet to be achieved. Norton's most accurate results used the nonlinear normal-mode technique.

Some insight into the ultimate limitations on accuracy has come from classical aerodynamics. There have been many theoretical, experimental and numerical studies of the weak aerodynamic sound generation or *Lighthill radiation* named after M. James Lighthill's celebrated pioneering work of 1952. This is a simple form of spontaneous imbalance. It is now known that in continuously stratified flows there are further forms of spontaneous imbalance, neither instability-related nor Lighthill-like. Recent work at the cutting edge of this problem can be found in papers by D. Muraki, R. Plougonven, C. Snyder, A. Viúdez, and F. Zhang, appearing in the literature from about 2007.

The spontaneous-imbalance literature gives us a clear answer, in the negative, to a classic question posed in 1980 by Edward N. Lorenz. Could there be an exact balance relation? Could there be unsteady stratified, rotating flows that evolve in such a way that freely propagating sound and inertia–gravity waves are completely absent? More precisely, is there a slow manifold within the full phase space that is an invariant manifold of the full dynamics? Evolution on such a manifold would be such that spontaneous imbalance vanishes exactly.

Lighthill's arguments are enough to show that such a situation is overwhelmingly improbable. Though falling short of rigorous proof, they amount to a very strong heuristic. They show that, whatever else is going on, unsteady vortical flows are practically certain to emit sound and inertia–gravity waves, albeit sometimes very weakly; and practically all the flows of interest are unsteady. This means that spontaneous imbalance is generically nonzero, even though it may often be very close to zero, implying in turn that the so-called 'slow manifold' within the full phase space must be an infinite-dimensional chaotic layer. Though astonishingly thin in places – over a far wider range of parameter values than could reasonably have been expected a priori, as shown by Norton's work, in some cases at least – it is not a manifold, which by definition is infinitesimally thin. Though sometimes astonishingly accurate, the concept of balance is inherently and fundamentally approximate. The layer is sometimes referred to, therefore, as the slow quasimanifold.

(Arguably, a self-contradictory term like 'fuzzy manifold' is best avoided. By its mathematical definition a *manifold* is a perfectly sharp, smooth hypersurface and not at all fuzzy. Thus 'fuzzy manifold' would add yet another item to the list of self-contradictory terms like 'variable solar constant' and 'asymmetric symmetric baroclinic instability' – which of course we inevitably have to live with but, perhaps, need not add to.)

The fact that spontaneous imbalance can take a variety of forms beyond those described by Lighthill's arguments does not change the conclusion that the slow quasimanifold is generically a chaotic layer. Adding to the repertoire of possible imbalance mechanisms can only reinforce that conclusion.

Balanced Models

As already indicated, the swinging modes of the elastic pendulum can be described in a simplified yet in some cases accurate manner by imposing a functional relation between bob speed and spring length, suitably chosen. This reduces the dimensionality of the dynamical system's phase space. Similarly, vortical flows can be described by simplified balanced models or balance models, so called. These are constructed by imposing a balance relation from the start, thereby forcing a true slow manifold into existence. The phase space of the original equations – usually taken as the hydrostatic 'primitive equations', so called – is collapsed into a smaller phase space, though still infinite-dimensional.

The initialization of a balanced model requires only a single scalar field to be specified, such as the mass field, or the PV field in the generalized sense. This scalar field is sometimes called the master field or master variable of the balanced

model, to which all other dependent variables are slaved diagnostically. The model has only one prognostic equation, involving only one true time derivative, the rate of change of the master variable. This rate of change is to be sharply distinguished from the diagnostic estimates of time derivatives that may be hidden inside the definition of the balance relation [5], such as the diagnostic estimates $\Psi_1, \Psi_2, \dots$ already mentioned.

Among those qualifying as balanced models in this standard sense are the models labeled quasigeostrophic theory, semigeostrophic theory, and the Bolin–Charney model, also called ‘the’ balance equations, in isentropic coordinates or in shallow water. In the Bolin–Charney model the master variable can equally well be taken as the mass or as the PV. Both are advected by the same velocity field, a velocity field that satisfies the generalized Bolin–Charney balance relation. Here, as implicitly above, the PV is the exact (Rossby–Ertel) PV and is to be evaluated with the same velocity field.

This property of having a single velocity field is unusual in balanced models. Unlike the Bolin–Charney model, most balanced models have different velocity fields to do different jobs. Semigeostrophic theory is a well-studied example. It has three separate velocity fields. The first advects PV and mass, the second evaluates energy and momentum, and the third evaluates the PV taken as the exact, Rossby–Ertel PV. This last fact is hidden from view in most expositions of the theory. Traditionally the model’s PV is written in terms of the second velocity field, complicating the appearance of the formula for PV and disguising its origin. The three velocity fields differ from each other by fractional amounts $O(Ro)$ where Ro is again the Rossby number.

Semigeostrophic theory has remarkable mathematical properties but is comparable to quasigeostrophic theory in having $O(Ro)$ errors relative to the primitive equations. (Semigeostrophic theory is, however, superior in some respects, such as describing frontogenesis, albeit inferior in others such as describing mesoscale vortices.) The property of having more than one velocity field – for want of a better term we may call it ‘velocity splitting’ – was thought until recently to be a property of all balanced models with the sole exception of the Bolin–Charney model. In all other cases, refining the accuracy was thought to reduce greatly, but not to eliminate, disparities between the velocity fields of a model.

All this was indeed known to be true not only of Norton’s and similar highly accurate balanced models, but true also of another important subclass of balanced models, namely all the Hamiltonian models that can be constructed by Salmon’s method. Semigeostrophic theory is one of these. In the 1980s Rick Salmon showed how to construct balanced from unbalanced models in a systematic way within the Hamiltonian framework. Within that framework one imposes a balance relation as a constraint on the full dynamics, preserving the symplectic geometry of phase space. The constraint is imposed not only on dynamical trajectories but also on functional variations about those trajectories. The resulting balanced models are thus guaranteed to inherit Hamiltonian structure, as well as being accurate to the same formal order in Ro as the imposed balance relation.

A reason for using the Hamiltonian framework is the control it provides over conservation principles. The

framework, properly applied, guarantees that the balanced model will exactly conserve mass, momentum, and energy as well as PV materially. However, there is a fundamental tension between balance relations and conservation principles. A balanced model tries to mimic vortical flows that in reality produce Lighthill radiation or other forms of spontaneous imbalance. The spontaneous imbalance must give rise to wave-induced fluxes of energy and momentum, none of which can be exactly described by the balanced model.

So if one forces a true slow manifold into existence by imposing a balance relation, while insisting that all conservation relations still hold, something has to give way. What gives way, as it turns out, is the concept of a unique velocity field. All balanced models constructed by Salmon’s method exhibit velocity splitting, usually into two separate velocity fields but sometimes, as with semigeostrophic theory, into three. For more detail see the [Further Reading](#) list.

Even if we abandon energy and momentum conservation, there remains a possible tension between balance and local mass conservation. This is because spontaneous imbalance involves local adjustments in the mass field. Until recently, it was thought that this explained why the most accurate non-Hamiltonian balanced models then known still exhibit velocity splitting in one form or another, albeit by tiny amounts. So it was a further surprise when, thanks to recent work by A.R. Mohebalhojeh, a class of highly accurate balanced models was discovered that are entirely free of velocity splitting, yet as far as we know pay no systematic price in terms of accuracy, within shallow-water dynamics at least. Each such model has a unique velocity field, just as does the far-less-accurate Bolin–Charney model. The unique velocity field advects and evaluates the exact PV, advects mass, and evaluates energy and momentum which latter, however, are not conserved. One consequence, though, is that the models possess exact Casimir invariants (*see Dynamical Meteorology: Potential Vorticity*).

These new balanced models have been collectively designated *hyperbalance equations*. In order to write these equations one has to use functional derivatives, which are nonlocal, as well as ordinary partial derivatives. This may perhaps explain why the hyperbalance equations were not discovered long ago.

It is still an open question whether there will prove to be a tradeoff between accuracy and local mass conservation if we go beyond shallow-water dynamics, toward multi-layer models and continuously stratified reality.

Note on Terminology

The reader is warned that the terms geostrophic balance and its shorthand form, geostrophy, are sometimes used in the literature to mean balance more accurate than geostrophic, i.e., more accurate than [eqn \[1\]](#). A common example is the self-contradictory phrase ‘geostrophic adjustment’, which refers to the mutual adjustment of the mass and velocity fields to approach balance or to stay close to balance – and balance, of course, in real fluid flow, nearly always means not geostrophy, [eqn \[1\]](#), but a more accurate balance within the

generic class [5]. The example of a circular vortex adjusting toward ageostrophic, gradient-wind balance while radiating inertia-gravity waves is enough to illustrate the point. As already mentioned, gradient-wind balance is the particular case of Bolin–Charney balance that applies to a steady circular vortex, equivalent to eqn [1] plus a correction term representing relative centrifugal force. Thus by implication we have another piece of self-contradictory terminology, ‘ageostrophic geostrophic adjustment’, unfortunately well established.

It may also be noted that the term adjustment is itself used in two distinct senses that are sometimes confused with each other. The first is Rossby or initial-condition adjustment, the mutual adjustment of the mass and velocity fields toward balance that occurs primarily because a system is started in an unbalanced state. The second is spontaneous adjustment, the continual mutual adjustment of the mass and velocity fields to stay close to balance in unsteady vortical flow, even after initial conditions are forgotten. This second process is far more subtle and sets the ultimate limitations of the balance concept itself, the degree of fuzziness of the slow quasimanifold.

For all the foregoing reasons, some authors are beginning to avoid the term geostrophic adjustment, instead using the terms Rossby adjustment or initial-condition adjustment in the first case, and spontaneous adjustment or spontaneous imbalance in the second.

The term semigeostrophic theory is used here in its standard sense, referring to the balanced model originally introduced by Brian J. Hoskins in 1975. The reader is warned that in Salmon’s papers the same term, semigeostrophic theory, is used in a different, more generic sense.

Baroclinic Instability

R Grotjahn, University of California, Davis, CA, USA

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

Baroclinic instability refers to a process by which perturbations draw energy from the mean flow potential energy. Conditions in the middle latitude atmosphere are conducive for zonally varying structures (eddies) to grow by this process. The baroclinic energy conversions are proportional to eddy heat fluxes; these eddies also accomplish some of the necessary poleward transport of heat, especially in middle latitudes. Baroclinically unstable solutions arising in simple linear quasigeostrophic formulations have properties similar to observed frontal cyclones. Improving those simplifying assumptions (such as allowing nonlinearity) improve the similarity between simulated and observed properties.

Introduction

Baroclinic instability draws energy from the portion of the potential energy available to be converted (referred to as 'available potential energy' or APE). APE is dependent upon a horizontal gradient of temperature. The conversions of energy are proportional to perturbation heat fluxes in the horizontal and vertical. From thermal wind balance, a horizontal temperature gradient implies the presence of vertical shear. So, baroclinic instability is also an instability of the vertical shear.

Another view of baroclinic instability emphasizes interacting potential vorticity (PV) anomalies. Baroclinic instability is often studied by linearizing the dynamics equations and using eigenvalue or initial value techniques. These alternative views and analysis procedures generally provide complementary means to understand better baroclinic instability.

The atmosphere requires heat fluxes to maintain the observed pattern of net radiation (positive in the tropics, negative poleward of 38° on an annual average). A zonal mean meridional circulation, such as a tropical Hadley cell, can generate these heat fluxes. The poleward moving air in the Hadley cell accelerates while conserving angular momentum. In contrast, lower tropospheric air is slower-moving. Hence, vertical shear builds toward the poleward edge of each Hadley cell. In middle latitudes, baroclinic instability provides a mechanism to explain how the eddies form and evolve whilst including and accomplishing the necessary heat fluxes. Theoretical models of baroclinic instability can simulate various observed properties of midlatitude eddies including the dominant length scales, propagation speed, vertical structure, and energetics.

An Illustrative Model

An illustrative model provides mathematical relations and archetype solutions for the concepts that follow.

Mathematical Formulation

The model uses quasigeostrophic (QG) approximations and nondimensional scaling appropriate for midlatitude frontal

cyclones. PV has contributions from the interior and from temperature gradients at rigid bottom ($z = 0$) and top ($z = Z_T$) boundaries. PV in the QG system (or QG PV) can be written:

$$q = \underbrace{\nabla^2 \psi + f_0 + \beta y}_{\text{RV}} + \underbrace{\gamma \frac{\partial \psi}{\partial z} + \varepsilon \frac{\partial^2 \psi}{\partial z^2}}_{\text{TV}} + \underbrace{\left\{ \varepsilon \frac{\partial \psi}{\partial z} \Big|_{z=0} - \varepsilon \frac{\partial \psi}{\partial z} \Big|_{z=Z_T} \right\}}_{\text{BPV}} \quad [1]$$

where

$$\varepsilon = \frac{f_0^2 L}{g \kappa D}, \quad \kappa = D \frac{\partial \ln \theta_s}{\partial z}, \quad \text{and} \quad \gamma = \frac{\varepsilon \partial \rho}{\rho \partial z} + \frac{\partial \varepsilon}{\partial z} \quad [2]$$

ψ is the horizontal velocity streamfunction, ρ is the density, g is the acceleration of gravity, κ is the static stability from the horizontal mean potential temperature. The coordinates are x eastward, y northward, and z upward. Nondimensional length scales are L in the horizontal and D in the vertical. f_0 is the constant part while β is the meridional derivative (approximated as a constant) of the Coriolis parameter.

An inherent horizontal length scale is the Rossby radius of deformation ($L_R = NHf_0^{-1}$) where N is the Brunt Väisälä frequency ($N^2 = g\kappa D^{-1}$) and $H = RTg^{-1}$ is the scale height (an inherent vertical length scale). Thus, $\varepsilon = (LH)^2 (L_R D)^{-2}$ relates the assumed scales L and H to L_R and D .

QG PV includes three distinct parts: absolute vorticity (AV) that includes relative vorticity (RV), 'thermal' vorticity (TV), and boundary PV (BPV). Positive PV is associated with an interior trough (in geopotential) and/or a warm surface (i.e., boundary) temperature anomaly.

When the vorticity and potential temperature conservation equations are combined, one obtains a time-dependent equation for QG PV conservation:

$$\left[\frac{\partial}{\partial t} + U \frac{\partial}{\partial x} \right] \left(\nabla^2 \Psi + \frac{1}{\rho} \frac{\partial}{\partial z} \left(\rho \varepsilon \frac{\partial \Psi}{\partial z} \right) \right) + \frac{\partial Q}{\partial y} \frac{\partial \Psi}{\partial x} = 0 \quad [3a]$$

with boundary conditions at the bottom and top

$$\left[\frac{\partial}{\partial t} + U \frac{\partial}{\partial x} \right] \left(\frac{\partial \Psi}{\partial z} \right) - \frac{\partial U}{\partial z} \frac{\partial \Psi}{\partial x} = 0 \quad \text{at } z = 0, Z_T \quad [3b]$$

'Basic state' variables are specified: U (independent of x) is zonal wind, and Q is the interior part of the QG PV; meridional and vertical velocities are zero. One can solve eqn [3] as

an initial value problem by specifying an initial streamfunction or PV.

An eigenvalue problem can be formulated from eqn [3]. A common approach assumes time and space dependence in this form:

$$\psi(x, y, z, t) = \text{Re}\{\phi(y, z) \exp(ik(x - ct))\} \quad [4]$$

for the 'perturbation' streamfunction being sought. This solution has zonal wavenumber k and complex phase speed c . The growth rate is given by $k \text{Im}\{c\}$. If U has no meridional variation, then one can assume a wavelike y dependence too: $\exp(iy)$. When meridional wavenumber l equals zonal wavenumber k , the solution is a 'square wave.' Perturbation velocities are defined as $u = -\partial\psi/\partial y$ and $v = \partial\psi/\partial x$.

Additional simplifying approximations are often made. A particularly simple form, commonly labeled the 'Eady model,' was described by E.T. Eady in 1949. The Eady model assumes wavelike meridional structure, $\partial Q/\partial y = 0$, $U = z$, incompressibility ($\rho = \text{constant}$), and $\varepsilon = 1$. Then eqn [3a] is reduced simply to solving $q' = 0$ in the interior where the prime denotes the 'perturbation' sought. The Eady eigenvalue problem can be solved analytically, yielding a pair of 'normal modes' one growing, one decaying for scaled wavenumber $\alpha < \sim 2.4$. The scaled wavenumber:

$$\alpha = \{(k^2 + l^2)\varepsilon^{-1}\}^{1/2} \quad [5]$$

is proportional to absolute wave number and static stability.

Equations for perturbation kinetic energy, K_e and available potential energy, A_e are:

$$\begin{aligned} \frac{\partial A_e}{\partial t} &\equiv \frac{\partial}{\partial t} \iiint \frac{\rho_S}{2} \left\{ \varepsilon \left(\frac{\partial \psi}{\partial z} \right)^2 \right\} dx dy dz \\ &= \underbrace{\iiint \varepsilon \rho_S \frac{\partial U}{\partial z} \frac{\partial \psi}{\partial x} \frac{\partial \psi}{\partial z} dx dy dz}_{(A_z \rightarrow A_e)} - \underbrace{\iiint \rho_S w \frac{\partial \psi}{\partial z} dx dy dz}_{(K_e \rightarrow A_e)} \end{aligned} \quad [6a]$$

$$\begin{aligned} \frac{\partial K_e}{\partial t} &\equiv \frac{\partial}{\partial t} \iiint \frac{\rho_S}{2} \left\{ \left(\frac{\partial \psi}{\partial y} \right)^2 + \left(\frac{\partial \psi}{\partial x} \right)^2 \right\} dx dy dz \\ &= - \underbrace{\iiint \rho_S U \left\{ \frac{\partial \psi}{\partial x} \frac{\partial \psi}{\partial y} \right\}_y dx dy dz}_{(K_z \rightarrow K_e)} + \underbrace{\iiint \rho_S w \frac{\partial \psi}{\partial z} dx dy dz}_{(A_e \rightarrow K_e)} \end{aligned} \quad [6b]$$

The volume integrals are over a closed domain. In the QG system, $\partial\psi/\partial z$ is proportional to potential temperature θ , making the first term on the right hand side of eqn [6a] proportional to a meridional heat flux, while the second term is proportional to a vertical heat flux. The specified vertical shear, $\partial U/\partial z$ is proportional to the available potential energy, A_z of the basic state and is the energy upon which the baroclinic instability mechanism feeds. The first term on the RHS of eqn [6b] is a barotropic energy conversion. The barotropic conversion is

Figure 1 Quasigeostrophic eigenanalysis. (a) Specified zonal wind U , and meridional gradient of interior potential vorticity Q_{0y} versus scaled height. $Z = 1$ is 10 km. (b) Growth rate and (c) phase speed vs absolute wave number α . (d)–(f) Amplitude A , and phase P , for the growing normal mode for $\alpha = 0.8$, $\alpha = 2.0$, and $\alpha = 3.0$, respectively. All three modes tilt westward (upstream) with increasing height. Dimensional wavelengths depend upon scaling assumptions, but reasonable choices imply that $\alpha = 0.8$, $\alpha = 2.0$, and $\alpha = 3.0$ correspond to 11, 4.4, and $\sim 2.9 \times 10^3$ km wavelengths respectively. (Zonal and meridional scales are set equal.) The same scaling implies phase speed of 9 m s^{−1} and doubling time of ~ 1.2 days for $\alpha = 2.0$. Figure 2 Initial value calculation. (a) Zonal cross section of initial streamfunction, dashed contours used for negative values. (b) Time series of growth rates for domain average potential enstrophy (solid line) and its components: RV^2 (short dashed line), TV^2 (dot-dashed line), and BPV^2 (long dashed line). Growth rates asymptote to the most unstable normal mode rate for this wavenumber ($\alpha = 2.0$). (c) Similar to (b) except for total energy (solid line), kinetic energy (short dashed line), and available potential energy (dot-dashed line).

proportional to the divergence of eddy momentum flux and also draws energy from the mean flow. The second term on the RHS of eqn [6a] and [6b] is the same but with opposite sign indicating a conversion between A_e and K_e .

Example Solutions

This QG eigenmodel of baroclinic instability is applicable to the midlatitudes. In these regions, zonal flow increases with height reaching a maximum near the tropopause. Figure 1(a) is a representative nondimensional profile of U where the tropopause is at nondimensional $z = 1.0$. The growth rate and phase speed spectra along with the (growing normal mode) eigenfunction structures for different k are shown in Figure 1 as well. The growth rate has maximum value at a specific value of α . The vertical structure tends to have relative maxima at the surface and near the tropopause, but it becomes progressively more bottom-trapped for shorter waves. The phase varies such that unstable modes tilt upstream with height, i.e., against the mean flow shear. Other solutions to eqn [3], labeled ‘continuum modes,’ are relevant to ‘nonmodal’ growth.

For shorter waves, the eigenmodes with lower level maximum tend to dominate (when compressibility is included) and the solution decays rapidly away from the boundary. For longer waves, the tropopause level maximum tends to dominate (Figure 1(d)). Eady model normal modes have interior $q' = 0$; from eqn [1]: the Laplacian increases as k^2 requiring a rapid change with height for short waves to make the thermal term comparable to the Laplacian term (this leads to boundary trapping of the solutions). For longer waves, the Laplacian

becomes small and the vertical structure is more evenly spread in the vertical, hence these modes are ‘deeper.’

Typical geopotential patterns observed prior to frontal cyclone development have separate surface and upper troposphere troughs, each equivalent barotropic (vertical trough axis), with the upper level trough more prominent. A crude simulation of that initial state is used to generate solutions shown in Figure 2. Time series of the growth rates of several quantities are tracked over several days. The time series include potential enstrophy ($H = (q')^2$) and total energy ($TE = A_e + K_e$) integrated over the whole domain. The solutions asymptote to the most unstable normal mode growth rate as that eigenmode emerges to dominate the solution. The growth rate has transient peak values that can exceed the asymptotic (normal mode) value.

Classical View

Baroclinic instability draws upon the APE of the environment in which an eddy sits. Since APE is related to a horizontal temperature gradient, and that in turn to the vertical shear, it can be viewed as a type of shear instability. One advantage of doing so is to make comparisons with barotropic instability, which draws energy from the horizontal shear. This view provides a link to eddy fluxes that are observed and necessary for each conversion.

As demonstrated in eqn [6], heat fluxes are necessary to have a baroclinic energy conversion. Horizontal heat fluxes imply that the temperature and mass (here ψ) fields are offset. The offset implies that the trough and ridge axes tilt upstream with elevation.

Figure 3 Schematic diagram showing distortion of an isentropic surface by a baroclinically amplifying frontal cyclone. Dotted lines used for objects underneath the three-dimensional isentropic surface. Surface high H, and low L, marked along with two representative contours of surface pressure. Trajectories of representative parcels in the warm air W, and cold air C. Subscript s denotes projection onto the bottom surface while Z denotes projection onto the meridional plane (where $x = 0$). The trajectories do not cross the isentropic surface but distort it. Initially the isentropic surface had negligible variation with x and looked like the current pattern at $x = 0$. The projections W_Z and C_Z seem to cross the initial isentropic surface but in fact are flattening it (which reduces A_z). Rising air is warm while sinking air is cold, which lowers the center of mass converting A_e into K_e .

The QG formulation above is adiabatic, so individual parcels conserve their potential temperature (θ) over time. For unstable modes, the horizontal and vertical eddy heat fluxes must distort the θ field over time as suggested schematically in Figure 3. An isentropic (θ) surface is drawn in three-dimensional perspective; it curves up and over colder areas and dips down over warmer areas. Prior to eddy development, the isentropic surface did not vary in the x direction and had a shape like its intersection with the wall at $x = 0$. The isentropic surface is distorted by flow around the high and low pressure centers and representative cold {C} and warm {W} trajectories are also drawn. When these trajectories are projected onto the $x = 0$ wall they appear to cross the initial zonal mean isentrope and have a slope that is typically half the slope of the mean isentrope. In fact, they are changing the zonal mean of the

isentrope to become more horizontal, thereby reducing the horizontal temperature gradient and thus reducing A_z . In this classical view, A_z is reduced while A_e is increased by increasing the zonal undulations of the isentropic surface. Another aspect is that colder air is sinking while warmer air is rising, a process that lowers the center of mass and thus converts A_e into K_e . To lower the center of mass, the parcel paths must have the vertical component indicated but they must also be less than the slope of the mean isentropes for instability to occur.

The classical view can incorporate latent heat release as follows. The bulk of the precipitation in a developing cyclone forms in the warm air sector of the storm. The release of latent heat further depresses the isentropic surfaces where there is poleward motion implying additional conversion of A_z into A_e and K_e .

Potential Vorticity View

The PV view of instability tracks how two or more PV anomalies interact in a way that causes growth of the PV anomalies. PV is a fundamental conserved quantity for adiabatic motions. The illustrative model is designed around QG PV conservation.

A PV pattern has an associated streamfunction and horizontal wind field. In general, eqn [1] implies that PV emphasizes smaller scale variations than the streamfunction field. Inverting eqn [1] obtains broad patterns of ψ associated with isolated packets of q . For example, PV anomalies in the upper troposphere have corresponding streamfunction extending through the whole troposphere (but somewhat larger amplitude at the level where q has maximum magnitude). The associated winds are displaced from a PV anomaly center by $1/4$ wavelength (~ 1000 km). A similar depiction can be deduced for a PV anomaly associated with a surface temperature gradient.

PV anomalies are created by flow across PV contours. Figure 4 illustrates how two sinusoidal PV anomalies can amplify each other. The PV gradient is reversed between the two levels, increasing with y at upper levels and decreasing with y at the surface. This pattern is consistent with upper tropospheric PV and the surface temperature gradient, respectively. (Recall

Figure 4 Baroclinic instability from interacting PV anomalies at two levels. A representative PV contour (dot-dashed line) is drawn at each level. Note that the meridional (y direction) PV gradient points opposite directions at the two levels. The offset is (a) $1/4$ wavelength and (b) $1/2$ wavelength. A typical wavelength might be 4000 km. Each anomaly has associated wind component parallel to the PV gradient; dashed arrows are winds from the lower PV anomaly, while solid arrows are from the upper anomaly. The winds created by each anomaly propagate that anomaly. In (a) each PV anomaly has a wind component that amplifies the undulation in the other anomaly (by having a nonzero wind at the center of the other anomaly), thereby causing growth. In (b) each PV anomaly has a wind component that augments the propagation of the other anomaly in the manner indicated by the broad arrows; this causes the anomalies to migrate to a phase offset like diagram (a).

that q is positive for either lower geopotential heights or warmer surface temperature.) The associated winds distort the PV pattern in a way that causes the PV pattern to propagate. However, the meridional wind associated with a PV anomaly is in quadrature with that anomaly so the PV cannot amplify itself. Growth is described simply as advection at the PV extrema that further amplifies the PV pattern. Since the associated winds extend beyond the elevation of the PV anomaly, there can be interaction between the PV anomaly and a second PV anomaly at another level. When the second PV anomaly is offset from the first as in Figure 4(a), the associated winds amplify the first anomaly.

This mechanism also explains how developing cyclones maintain a preferred tilt (i.e., become 'phase locked'). The lower anomaly is shifted horizontally to the right in Figure 4(b) so that upper and lower anomalies are 180° out of phase. The two PV anomalies no longer amplify each other's PV anomalies (shutting off the instability mechanism). Furthermore, the two anomalies reinforce the velocities midway between their positive and negative extremes, thereby enhancing the propagation at each level; but the propagation is directed oppositely at each level, thereby reducing the phase

shift to reestablish the pattern in Figure 4(a). As with the classical view, normal modes are a special case where this phase locking is optimized.

The PV view provides theoretical weight to a classic description of how cyclones develop: an upper level trough (PV anomaly) approaches a low-level baroclinic zone (another PV anomaly), and then growth commences. This paradigm is commonly labeled 'type B' cyclogenesis.

The 'type B' cyclogenesis is illustrated in Figure 5 using a QG nonlinear model. A nearly nondeveloping, nearly coherent upper tropospheric trough is propagating in a flow with vertical shear and is approaching a localized region of warmer surface temperature. The surface warm anomaly is also a positive anomaly of PV in the lower troposphere. The trough has maximum amplitude in the upper troposphere, so there are associated cold anomaly in the troposphere and warm anomaly in the stratosphere. The trough is a region of positive PV. Differential vorticity advection and warm air advection cause rising motion (of cold air) ahead of the trough. Analogously, sinking motion occurs behind the trough. Hence there is positive baroclinic conversion behind and negative ahead of the trough. Integrated over the whole system the net baroclinic

Figure 5 (a)–(e) Zonal cross sections (East–West direction, x versus elevation, z) showing properties across the midpoint of a nearly coherent, nongrowing, upper level trough similar to those observed. z is scaled by 10 km and x by 1000 km. Eddy: (a) streamfunction; (b) temperature; (c) vertical motion, positive upwards; (d) quasigeostrophic potential vorticity; and (e) baroclinic energy conversion shown. The baroclinic energy conversion averaged over the whole upper trough is zero. (f) Schematic zonal cross section of interaction between upper trough encountering a near surface warm anomaly. The upper trough T moves in the direction of the solid arrow. The trough has eddy temperatures indicated by C for colder air, and W for warmer air. Hollow arrows show vertical motions. In the along-flow direction (x) there is upward motion ahead of the trough reaching a maximum near $z \sim 0.6$. Vertical motion is driven both by temperature advection (from $0.6 < z < 1.4$) and differential vorticity advection (from $0.3 < z < 0.7$). The associated divergence is indicated by solid ovals and convergence by dashed ovals. From the quasigeostrophic vorticity equation, these divergence fields oppose vorticity advection by the mean flow at upper levels, and enhance that advection at lower levels. Hence, the trough maintains its vertical tilt in the presence of vertical shear in the zonal mean wind ($U(z)$). The sign of the baroclinic energy conversion, BCE is indicated by open + and - signs. The upper pattern of BCE is similar to panel (e). However, when the upward and poleward motion ahead of the upper trough encounters the warm anomaly, the vertical motion is locally enhanced as is the meridional heat flux. There is net generation of vorticity, net BCE, and the eddy begins to grow. Adapted with permission from Grotjahn, R., 2005. Quarterly Journal of the Royal Meteorological Society 131, 109–124. <http://dx.doi.org/10.1256/qj.03.163>.

conversion is zero. The vertical motion requires divergence and convergence above the peak rising motion. From the QG vorticity equation convergence opposes the positive vorticity advection ahead of the trough at upper levels (reinforces it at lower levels) and in so doing maintains the vertical tilt of the trough even though the advecting wind speed increases with height. When the upper trough begins to encounter the low-level warm anomaly, the warm advection in the poleward flow ahead of the trough is increased. Initially at lower levels, this warmer air rises (instead of the cold air) causing the baroclinic conversion ahead of the upper trough to become less negative and even positive, and the system begins to amplify.

Observations show independent troughs at upper and lower troposphere prior to development with the upper approaching the lower. Neither trough has upstream tilt initially, such tilt emerges only after the two become favorably aligned and growth has commenced.

A necessary condition for instability is that the across-flow mean gradient of PV change sign within the domain. In the illustrative model (Figure 3) and (Figure 4), $\beta > 0$ means that $Q_y > 0$ in the interior, and the surface temperature gradient ($d\theta/dy < 0$) implies that $Q_y < 0$ at the ground. In the Eady model $Q_y = 0$ everywhere in the interior, so the normal mode instability comes from BPV having opposite sign at top and bottom boundaries.

A necessary condition for instability is that a steering level, where $U = \text{Re}\{c\}$, lie within the domain. A supportive kinematic argument is that air parcels remain with the system (rather than blow through it or be left behind) and are more easily mixed laterally. For really long waves, strong retrogressive motion caused by the β -term leads to a different class of unstable eigenmodes for $\alpha < \sim 1.1$ (note cusp in Figure 1(b)) than for larger α .

The eddy meridional flux of potential vorticity is also linked to $\nabla \cdot \mathbf{F}$ in QG theory, where $\mathbf{F}$ is the Eliassen–Palm flux. In addition, due to the strong meridional eddy heat flux present in a baroclinically growing eddy, $\mathbf{F}$ has an upward pointing component. From wave theory, specifically the ‘generalized Eliassen–Palm relation,’ the upward pointing EP flux provides an explanation for upper level amplification of the eddy as it grows nonlinearly.

Normal Modes

Normal modes are physically meaningful eigenfunctions. As in the illustrative model, the equations are linearized about a specified basic state and perturbation solutions are sought. Most commonly, the time and one or more space dependencies are assumed. By assuming a form like eqn [4], unstable solutions grow exponentially. Simple enough models may be solved analytically. More commonly, the eigenvalue problem is solved numerically.

Normal modes are consistent with many observed features:

1. Unstable modes tend to be lined up along the jet axis (if present) in the mean flow.
2. The most unstable wavelength is similar to the observed median size. The normal mode scale can be manipulated by varying the choices made for nondimensional parameters, but is on the order of 4500 km.

3. Solutions tend to develop similar zonal and meridional lengths, the latter responds to the width of the jet providing one natural scale in the model. Other properties (like static stability) also influence the length scales.
4. The vertical structure of the most unstable modes tends to have relative maxima at the surface and upper troposphere.
5. In growing normal modes the temperature lags the mass field in the lower troposphere (typically by 20–50° of phase for the most unstable mode). Two consequences are as follows: First, troughs and ridges in the mass field must be displaced (i.e., tilt) upstream with increasing elevation. There is typically 1/4–1/2 wavelength ($1\text{--}2 \times 10^3$ km) between the trough location at the surface and at tropopause level. Second, the lag allows across-flow heat fluxes down the temperature gradient, as expected from eqn [6a], even for geostrophic winds. In the Eady model the heat flux is uniform with height. Model improvements, most notably compressibility, can emphasize the eddy heat flux in the lower troposphere (where observations find it most prominent).
6. The rate of propagation is $\sim 10\text{--}20$ m s^{−1}: slower than jet stream level winds, but faster than (zonal average) surface winds. A steering level is defined as where the propagation speed of the storm equals the wind component along the storm’s track. The steering level for the most unstable, normal modes is typically between 700 and 500 mb depending on the assumptions made. For shorter waves, the steering level is closer to the surface since these modes move slower. Longer waves respond to competing effects: they have greater upper level amplitude (where U is faster) but greater sensitivity to β (which enhances retrograde motion).
7. The rate of growth is similar to but slower than that of observed cyclones. Observed doubling times are typically 1–2 days at upper levels.
8. Instability is inversely proportional to static stability. For example, the peak growth rate depends on α ($=2.0$ in Figure 1). From eqns [2] and [5], α is proportional to static stability κ . Hence, smaller κ places the most unstable peak at larger k making the growth rate ($k \text{Im}\{c\}$) larger. Kinematically, vertical motion needed in eqn [6] becomes easier for smaller κ .

The fact that normal modes have fixed tilt is not necessarily unrealistic. Observations of the vorticity equation terms support an approximately fixed structure for developing low because the divergence term opposes the horizontal advection at upper levels but reinforces the horizontal advection at low levels. The normal modes (Figure 1) are special structures where the net motion is exactly uniform throughout the depth of the fluid. Tracking observed frontal cyclone troughs over time shows evidence that such storms maintain a roughly fixed tilt during their growth. The vorticity equation also illustrates instability whereupon the divergence term has positive vorticity tendency at a trough where vorticity is a maximum thus amplifying the peak vorticity (and vice-versa for ridges).

In addition to the normal modes, the eigenfunctions include a class of solutions called ‘continuum’ modes. For an adiabatic model, continuum modes have equivalent barotropic structure (no tilt) making them neutral. In the Eady model, continuum modes have zero PV at all levels except at the critical

level, where their amplitude has a 'kink.' Continuum modes play a role in nonmodal growth.

Nonmodal Growth

Nonmodal growth is seen when solving initial value problems like eqn [3]. The formulation can be linear as in eqn [3] or nonlinear. This approach is more general than eigenanalysis since the time dependence is not assumed as it is in eqn [4].

The solution at any time can be decomposed into a combination of eigenfunctions. For an arbitrary initial state, continuum and normal modes are present. These modes move at differing speeds. In a linear formulation the modes operate independently; as modes disperse, positive and negative reinforcement varies. The interference between modes decays algebraically asymptotically. However, for some initial conditions it is possible to have sizable growth over a limited time period.

For the Eady model, analytic solutions can be found which illustrate the process. Using an initial condition with upstream tilt ($\phi \sim \exp(imz)$ in eqn [4] where $m > 0$) yields solutions with normal mode and algebraic parts. The algebraic part has time dependence proportional to $\{(m - kt)^2 + \alpha^2\}^{-1}$ and $\exp\{i(m - kt)z\}$. The amplitude increases while the upstream tilt

becomes more vertical until $t = mk^{-1}$. After that, the wave tilts downstream and decays.

Initial upstream tilt becoming more vertical with time has led to an expectation that RV increases at the expense of TV while interior PV remains conserved. However, exceptions can be found where large nonmodal growth occurs (in H) as upstream tilt *develops* from an initial state with no tilt. The explanation lies in a rough cancellation between RV and TV leaving the BPV evolution to dictate rapid growth in H .

A robust interpretation of nonmodal growth is the progressively more favorable superposition of constituent modes. Continuum modes having mainly upper level amplitude tend to move fast, while modes with mainly lower level amplitude move slowly. Decomposition into eigenmodes of an initial state with upstream tilt finds faster continuum modes located upstream of slower continuum modes. Over time, the modes become more favorably lined up; the tilt becomes more vertical and the total amplitude increases. Figure 6 illustrates the process.

Nonmodal growth can be quite strong in simple models like Eady's. However, most improvements to the model such as adding compressibility, variable Coriolis, and realistic vertical shear of U reduce nonmodal growth. Using more realistic initial states also tends to reduce nonmodal growth (e.g., using a wave packet instead of a wavetrain; using separate untilted upper and lower features instead of connecting them with a tilt).

Figure 6 Nonmodal growth as a superposition process. Four initial value linear calculations are shown. The top three rows show three individual neutral continuum modes at three times. The bottom row used the sum of the three modes at the initial time. (a) Initial condition, time = 0, (b) time when energy growth is a maximum in the sum, time = 1, and (c) time when growth rate is zero in the sum, time = π . Other Issues

Baroclinic instability has links with barotropic instability. First, each instability draws energy from mean flow shear. Second, barotropic instability has a similar stability criterion (AV gradient changing sign in the domain). Third, there can be interference between the two instabilities. The most unstable baroclinic eigenmode has optimal structure for a flow having the vertical shear alone, but when horizontal shear is added to that flow a different structure is needed otherwise the eddy will be sheared apart. The subsequent structure is unlikely to be as optimal for baroclinic energy conversion. Hence, the baroclinic conversion will usually be reduced, though the barotropic growth mechanism may compensate. Figure 7(c) illustrates such a calculation; in this case adding a purely barotropic flow reduced the growth rate even though the barotropic growth mechanism was activated.

Baroclinically unstable frontal cyclones prefer to develop in certain regions. The preference may arise from local conditions such as lower static stability or locally greater vertical shear. The illustrative model above assumes a wavetrain solution; when more localized development is considered, a variety of issues are raised.

For example, if one uses a single low as the initial condition, the solution typically evolves into a chain of waves as the modal constituents of the initial state disperse. Alternatively, a wave packet initial condition might be used consisting of a 'carrier wave' multiplied by an amplitude envelope. The packet evolution depends upon the mean flow properties and assumptions made in the model. However, for reasonable

choices of parameters, one might find a packet that spreads while propagating downwind. The leading edge of the packet has mainly faster, wider, and deeper modes. The trailing edge has slower, shorter, and shallower waves. It is possible to construct a localized structure, which resists this dispersion by making a judicious combination of eigenmodes having similar phase speed, but different zonal wavenumber. One such example was used when discussing 'type B' cyclogenesis (Figure 5). Figure 8 illustrates another example using neutral continuum modes. When this model is solved as an initial value problem the packet maintains a localized shape for a long time and almost no growth occurs since the normal modes were filtered out and there is very slow phase shifting of the constituent modes. However, when nonlinear advection is allowed, modes interact and soon amplitude is injected into all the eigenmodes including the growing normal modes, which grow rapidly in this example.

Studies of regional development spawned subcategories of baroclinic instability. 'Absolute' instability occurs when the wave packet expands faster than it propagates; the amplitude at a point keeps growing. 'Convective' (in the advection sense) instability occurs when the packet moves faster than it spreads so that growth then decay occurs as the packet moves past a point. 'Global' instability (like the eigensolutions shown here) has growth that is invariant to a Galilean transform. Such is not the case for 'locally' unstable modes. Normal modes for zonally varying basic states look like carrier waves modulated by a spatially fixed amplitude envelope; the envelope locally modifies the growth rate (sometimes called 'temporal' instability); enhancing the global growth locally where the carrier

Figure 7 Baroclinic energy conversion ($A_2 \rightarrow A_6$) for four models. (a) Lowest order, square wave solution for an Eady-type model but including compressibility, increasing vertical shear in U , $\beta = 1$. (b) Solution when a surface frontal zone, centered at $y = 0$, is added to the lowest order mean flow U_0 and leading ageostrophic advective effects are included (using geostrophic coordinates). The frontal zone adds wind field: $0.2(2z - z^2) U_1$ where $U_1 = b_1(1 - \tanh^2(\alpha y)) - b_2 - 3b_3 y^2$ to U_0 . The geostrophic coordinate transform causes the asymmetry. (c) Modification to the conversion shown in (a) when barotropically unstable horizontal shear U_1 is added to U_0 . If the total wind is $U = U_0 + \mu U_1$, then the total conversion is (a) + μ (c). The barotropic shear reduces the growth rate. (d) Modification due to all leading order ageostrophic corrections. If those corrections are order μ , then the total conversion is (a) + μ (d). Ageostrophic conversions reduce the conversion and introduce asymmetry. Adapted with permission from Grotjahn, R., 1979. Journal of Atmospheric Sciences 36, 2049–2074.

Figure 8 Initial value calculations for a linearly localized initial condition. (a) Zonal cross section showing contours of streamfunction initially. Values < -1.0 are shaded. (b) Horizontal pattern of streamfunction at tropopause level ($z = 1.0$) initially. Initial condition constructed from neutral modes having similar phase speed. Growing or decaying normal modes are excluded. (c) Time series of energy growth rate for three integrations. Linear model (dotted line) showing little growth since the nonmodal mechanism is weak and growing normal modes cannot develop. Also shown are nonlinear calculations for two amplitudes of the initial condition, where the solid line uses three times the initial amplitude of the dot-dashed line. Growing normal modes are activated by nonlinear interaction. Some evidence of nonlinear saturation is seen.

wave propagates from lower to higher amplitude of the envelope. ‘Spatial’ instability allows wave number to be complex while phase speed remains real.

Nonlinear calculations raise other issues related to baroclinic instability. One issue concerns equilibration. The growing wave modifies the mean flow while drawing energy from it. This places a limit upon the cyclone development. In PV theory, this may be where the distortion shown in [Figure 4](#) becomes comparable to the cyclone width. Waves longer than the most unstable wave tend to reach larger amplitude than the linearly most unstable mode. One reason why is that they are deeper and so can potentially tap more APE in the mean flow. Another reason may be the larger scale in both horizontal dimensions provides a longer time for PV contour distortion. Another reason concerns the inversion of a PV anomaly: the streamfunction amplitude is larger for a broader PV anomaly.

‘Life cycle’ studies model cyclones from birth to peak amplitude to decay. These studies typically find baroclinic growth followed by barotropic decay. This cycle fits the observed facts that eddies have a net heat flux and a net momentum convergence. These studies also reveal a characteristic evolution of the eddy structure: upper level amplification compared to the linear eigenmodes. An explanation is that saturation is reached sooner at the critical level and at the surface while upper levels continue to grow. Another was given above regarding the Eliassen–Palm flux F . When averaged over the life cycle, the vertical distribution of the zonal mean eddy heat and momentum fluxes becomes more realistic.

Finally, the atmosphere has higher order processes than the QG system. The biggest impact of ageostrophy is to break symmetries in the solutions. [Figure 7\(d\)](#) shows the leading order ageostrophic effects for a linear model. Ageostrophy causes enhanced eddy development on the poleward side (mainly by negative baroclinic conversion on the equatorward side), builds mean flow meridional shear, and slows down the wave. Ageostrophy also causes contours to be more closely spaced around a low and more widely spaced around a high.

Introduction

The Coriolis force arises when Newton's equations of motion are written in a rotating coordinate system. It is named for Gaspard-Gustave de Coriolis (1792–1843). His studies of dynamical problems associated with rotating machinery were presented to the Académie des Sciences in Paris in 1831.

All of the terms in the equations of motion related to the Coriolis force were actually included in the tidal equation of PS Laplace, published in 1775 and 1776, and repeated in Book IV of his *Treatise on Celestial Mechanics*, published in 1799.

Newton's equation of motion for a particle is

$$m \frac{d\vec{v}}{dt} = \vec{F} \quad [1]$$

where m is the mass of the particle, $\vec{v} = d\vec{r}/dt$ is the velocity of the particle, $\vec{r}$ is the position vector, and d/dt is the time derivative following the motion of the particle. The quantity $\vec{a} = d\vec{v}/dt$ is the acceleration. This equation holds in an inertial reference frame, fixed with respect to the 'fixed' stars.

But the Earth on which mankind lives rotates at a nearly constant rate about an axis whose direction is more or less fixed in inertial space. The Earth's rotation vector is denoted by $\vec{\Omega}$, so $\Omega = |\vec{\Omega}|$ is the rotation rate. The direction of $\vec{\Omega}$ points from the South Pole to the North. The Earth rotates once each sidereal day, which is about 8.62×10^4 solar seconds. So the Earth's rotation rate is $\Omega = 7.29 \times 10^{-5} \text{ s}^{-1}$.

The motions of the atmosphere and the oceans are generally described in a coordinate system which rotates with the Earth. For example, longitude, latitude, and height above a reference geopotential surface form a convenient rotating system. Because the Earth is rotating, it bulges at the equator and is flattened at the poles. The reference geopotential includes both the gravitational and centrifugal potential, so the reference surface is not quite spherical. The Earth's equatorial radius exceeds the polar radius by about 21 km. Both the shape of the geopotential and the Coriolis force depend on the Earth's rotation rate.

Derivation of the Coriolis Force

Consider two coordinate systems, one of which is inertial, fixed with respect to the fixed stars; and the other rotating with angular velocity $\vec{\Omega}$. A prime is used to denote a quantity as viewed in the rotating frame and use unprimed quantities to denote the inertial frame. Let $\vec{q}$ be a fixed vector in the inertial frame, so that

$$\frac{d\vec{q}}{dt} = 0 \quad [2]$$

Viewed in the rotating frame, $\vec{q}'$ appears to rotate with angular velocity $-\vec{\Omega}$ in the direction opposite to the rotation of the coordinate system. So its apparent velocity in the rotating system is $-\vec{\Omega} \times \vec{q}'$, and $+\vec{\Omega} \times \vec{q}'$ must be added to this apparent velocity to bring it to zero. This leads to the rule

$$\frac{d}{dt}\vec{q} = \frac{d}{dt'}\vec{q}' + \vec{\Omega} \times \vec{q}' \quad [3]$$

where the terms on the left are viewed in the inertial frame and those on the right in the rotating frame. Furthermore, this same result, eqn [3], holds even if the left-hand side is not zero.

Consider a particle with position vector $\vec{r}$ in the inertial frame and $\vec{r}'$ in the rotating frame. The velocity is given by

$$\vec{v} = \frac{d\vec{r}}{dt} = \frac{d\vec{r}'}{dt'} + \vec{\Omega} \times \vec{r}' = \vec{v}' + \vec{\Omega} \times \vec{r}' \quad [4]$$

and the acceleration is

$$\begin{aligned} \vec{a} &= \frac{d\vec{v}}{dt} = \left(\frac{d}{dt'} + \vec{\Omega} \times \right) (\vec{v}' + \vec{\Omega} \times \vec{r}') \\ &= \frac{d\vec{v}'}{dt'} + 2\vec{\Omega} \times \vec{v}' + \vec{\Omega} \times \vec{\Omega} \times \vec{r}' \end{aligned} \quad [5]$$

The first term on the right is the acceleration as seen in the rotating system. The second term is the Coriolis acceleration. The third term is the centripetal acceleration arising from the rotating coordinate frame.

Modification of the Gravitational Potential

Let

$$R^2 = \vec{r}' \cdot \vec{r}' - \frac{1}{\Omega^2} (\vec{\Omega}' \cdot \vec{r}')^2 \quad [6]$$

Then R is the distance from the position $\vec{r}'$ to the axis of rotation, and it is easy to check that

$$\vec{\Omega}' \times \vec{\Omega}' \times \vec{r}' = \nabla' \left(-\frac{\Omega^2 R^2}{2} \right) \quad [7]$$

Since this is the gradient of a scalar, it can be combined with the gravitation potential to define an effective gravitational potential. This then accounts for the nonspherical shape of the rotating Earth and the reduction of the strength of the apparent gravitational force due to the centripetal acceleration.

Motions on a Rotating Earth

We now consider motions as observed on a rotating Earth, and drop the primes used earlier to denote the rotating coordinates.

Consider a local Cartesian coordinate system fixed with respect to the rotating Earth. Let x be positive toward the east, y positive toward the north, and z positive upward, opposite to the direction of the apparent gravitational force. Let $\hat{i}$, $\hat{j}$, and $\hat{k}$ be unit vectors in the directions of x , y , and z , and let u , v , and w be the components of the velocity in those directions. If particle motion is being considered then u , v , and w are the components of the particle velocity. If fluid motion is being considered then they are the components of the velocity of the fluid element at the positions x , y , and z . Let the origin of this system be at latitude θ_0 , which is the angle between the Earth's equatorial plane, and the local vertical direction. Then the Earth's rotation vector $\vec{\Omega}$ written in the local coordinate system is

$$\vec{\Omega} = \Omega \cos \theta_0 \hat{j} + \Omega \sin \theta_0 \hat{k} \quad [8]$$

The Coriolis force $\vec{F}_C = -2\vec{\Omega} \times \vec{u}$ is given by

$$\vec{F}_C = -2\Omega[(-\cos \theta_0 w + \sin \theta_0 v)\hat{i} - \sin \theta_0 u\hat{j} + \cos \theta_0 u\hat{k}] \quad [9]$$

This force is perpendicular to $\vec{u}$ (and to $\vec{\Omega}$) and therefore does no work on the moving particle or fluid. In the equation for the time rate of change of kinetic energy the Coriolis terms vanish identically. This is important to note because in most problems the part of the Coriolis force proportional to the locally horizontal component of $\vec{\Omega}$ can be shown by a scaling argument to be negligible. These are the terms proportional to $2\Omega \cos \theta_0$. When they neglected the $-2\Omega \cos \theta_0 \hat{w}$ term and the $+2\Omega \cos \theta_0 u\hat{k}$ term must both be omitted to avoid introducing a spurious source of kinetic energy. Likewise, if one of these terms is important then the other should be included as well. If these terms are omitted then the only quantity involving the rotation is $f_0 = 2\Omega \sin \theta_0$. This is called the Coriolis parameter. More generally,

$$f = 2\Omega \sin \theta \quad [10]$$

is the Coriolis parameter at latitude θ .

The f -Plane and the Beta Plane

If the problem under consideration involves a physical domain that includes the whole globe or a large portion of it, then spherical coordinates are a natural choice and the full dependence of the Coriolis force on latitude is retained. If the latitudinal extent of the physical domain is small enough that $f = 2\Omega \sin \theta$ is nearly constant, then f is approximated by the constant f_0 and studying the problem 'on an f -plane' is spoken of.

A more common situation which arises in both meteorology and oceanography is one in which the latitudinal extent of the domain is large enough so that the spatial variation of $f = 2\Omega \sin \theta$ needs to be considered, but the full spherical geometry does not. Then the latitude is written as $\theta = \theta_0 + y/R$, where R is the radius of the Earth and $\sin \theta$ is approximated by the first two terms in its Taylor expansion. It is written as

$$f = 2\Omega \sin \theta \approx 2\Omega \sin \theta_0 + \frac{2\Omega}{R} \cos \theta_0 y = f_0 + \beta y \quad [11]$$

The approximation $f = f_0 + \beta y$ is called the beta plane approximation. The parameter $\beta = (2\Omega/R) \cos \theta_0$ was first introduced by Carl Gustav Rossby in 1939.

Examples: The Foucault Pendulum

We now turn to some simple examples to illustrate the effect of the Coriolis force. The examples are the Foucault pendulum, inertial oscillations, Ekman layers, and geostrophic balance. For the Foucault pendulum, let a particle of mass m be suspended by a string of length ℓ . Take the origin at the equilibrium position of the mass, directly below the point of suspension. If the horizontal displacements are small compared to ℓ , then the x and y components of the tension in the string are approximately $-mg(x/\ell)\hat{i}$ and $-mg(y/\ell)\hat{j}$. In the absence of rotation the equations of motion would be $m\ddot{x} = -m(g/\ell)x$ and $m\ddot{y} = -m(g/\ell)y$, where the dots denote a time derivative. If the Coriolis force term is added and divided by m then is obtained

$$\ddot{x} - f\dot{y} + \omega^2 x = 0 \quad [12]$$

and

$$\ddot{y} + f\dot{x} + \omega^2 y = 0 \quad [13]$$

where $\omega^2 = g/\ell$ is the pendulum frequency in the nonrotating system. For positive f , it is seen that the effect of the Coriolis force is to accelerate the particle to the right of its motion. A solution of eqns [12] and [13] with initial conditions $x = x_0$, $y = 0$, $\dot{x} = 0$, and $\dot{y} = 0$ at $t = 0$ is given by

$$x + iy = x_0 \exp\left\{-i\frac{ft}{2}\right\} \left[\cos \omega't + \frac{if}{2\omega'} \sin \omega't\right] \quad [14]$$

where complex notation and $\omega'^2 = \omega^2 + f^2/4$ have been used.

The term in the square bracket describes an elliptical orbit, almost rectilinear if $f' \ll \omega'$, with the pendulum oscillating at frequency ω' . The exponential term indicates that this elliptical orbit slowly rotates clockwise in the Northern Hemisphere, at frequency $f/2$. This rotation is due to the deflection of the orbit by the Coriolis force. The frequency $f/2 = \Omega \sin \theta$. At the North Pole, the period of the exponential terms is 24 h, and can be thought of as the Earth rotating under the swinging pendulum.

Note that the solution given by eqn [14] never passes through the origin. A slight change in initial conditions, with $x = x_0$, $y = 0$, $\dot{x} = 0$, and $\dot{y} = -f/2x_0$ at $t = 0$, produces the solution

$$x + iy = x_0 \exp\left\{-i\frac{ft}{2}\right\} [\cos \omega't] \quad [15]$$

The $[\cos \omega't]$ represents a true rectilinear orbit through the origin and the exponential factor describes the rotation of the plane of the orbit; the nonzero initial value of $\dot{y}$ gives the pendulum just the correct initial velocity to produce this solution.

In the Foucault pendulum problem, the Coriolis force is a relatively small perturbation on the orbit of the pendulum as it goes back and forth once, but over the course of a day it has a substantial cumulative effect. In most atmospheric and oceanic problems, interest is shown on timescales of a day or longer. The Coriolis force then becomes one of the dominant terms in the equations of motion. In the remaining illustrations the Coriolis term is balanced by various other possible important terms.

Geostrophic Balance

If the motions are varying slowly enough with time to be regarded as nearly steady, and turbulent dissipation is small, then the approximate balance in the horizontal momentum equation is

$$+\frac{1}{\rho}\frac{\partial p}{\partial x} = fv \quad [16]$$

and

$$+\frac{1}{\rho}\frac{\partial p}{\partial y} = -fu \quad [17]$$

where p is pressure, ρ the density, and u , v , and f the velocity components and the Coriolis parameter. Equations [16] and [17] show that the pressure gradient on the left balances the Coriolis force on the right. This is called geostrophic balance and is illustrated elsewhere in this encyclopedia (see **Dynamical Meteorology: Overview**, Figure 1). So, if the pressure field is known then the horizontal velocities can be estimated from eqns [16] and [17].

Inertial Oscillations

Various departures from geostrophic balance are possible, and for many of these the Coriolis force still plays a dominant role. Inertial oscillations provide one such example. In the simplest case, horizontal pressure gradients are ignored and horizontal accelerations by the Coriolis force are balanced. The governing equations are

$$\frac{du}{dt} = fv \quad [18]$$

and

$$\frac{dv}{dt} = -fu \quad [19]$$

If the initial condition is $u = U_0$, $v = 0$, then the solution is

$$u = u_0 \cos(ft) \quad [20]$$

$$v = -u_0 \sin(ft) \quad [21]$$

or in complex form

$$u + iv = u_0 \exp\{-ift\} \quad [22]$$

Equation [22] clearly shows that the velocity vector rotates at frequency f , clockwise in the Northern Hemisphere and counterclockwise in the Southern. Such oscillations have been observed in the sea.

One such observation lasting nearly a week was made in the Baltic Sea by Gustafson and Kullenberg. It is described in some detail by Sverdrup, Johnson, and Fleming in their book *The Oceans* (see Figure 1).

Ekman Layers

Another important example is the Ekman layer, where the Coriolis force is balanced by vertical mixing. The original work, published by V Walfrid Ekman in 1905, is called *On the*

Figure 1 Rotating currents of period one-half pendulum day observed in the Baltic Sea and represented by a progressive vector diagram for the period, 17–24 August 1933, and by a central vector diagram between 06.00 and 20.00 on 21 August (according to Gustafson and Kullenberg). Adapted from Sverdrup, H.U., Johnson, M.W., and Fleming, R.H., 1942. *The Oceans: Their Physics, Chemistry and General Biology*. New York, NY: Prentice-Hall.

Influence of the Earth's Rotation on Ocean Currents. Ekman considered the problem of determining the motion of the upper layer of the ocean due to a wind stress acting on the sea surface. Let z measure distance positive upward from the sea surface, so the domain of interest is $z < 0$. In this model, the only horizontal forces acting on the fluid are the Coriolis force and the divergence of the stress tensor describing the turbulent mixing. The stress is modeled in terms of an eddy viscosity as

$$\tau_z^x = \mu \frac{du}{dz} \quad [23]$$

and

$$\tau_z^y = \mu \frac{dv}{dz} \quad [24]$$

where τ_z^x means the stress in the x direction acting on a surface whose normal is in the z direction. The quantity μ is the

coefficient of eddy viscosity and $\nu = \mu/\rho$ is taken as a constant. The equations of motion in the x and y directions are

$$-fv = \frac{\partial}{\partial z} \left(\nu \frac{\partial u}{\partial z} \right) \quad [25]$$

and

$$fu = \frac{\partial}{\partial z} \left(\nu \frac{\partial v}{\partial z} \right) \quad [26]$$

If a stress of magnitude τ_x^0 acts in the x direction on the sea surface, the boundary conditions are

$$\nu \frac{\partial u}{\partial z} = \frac{\tau_x^0}{\rho} \quad \text{on } z = 0$$

and

$$\nu \frac{\partial v}{\partial z} = 0 \quad \text{on } z = 0 \quad [27]$$

Furthermore, the stresses are assumed to vanish as $z \rightarrow -\infty$. If it is written as

$$q = u + iv \quad [28]$$

then eqns [25] and [26] can be combined in the form

$$\nu q_{zz} = ifq \quad [29]$$

and for $f > 0$ (Northern Hemisphere), a solution which vanishes as $z \rightarrow -\infty$ is

$$q = A \exp \left\{ \frac{(1+i)}{\sqrt{2}} \sqrt{\frac{f}{\nu}} z \right\} \quad [30]$$

Applying the boundary condition given in eqn [27] determines A , and the solution is

$$q = u + iv = \frac{\tau^0}{\rho} \sqrt{\frac{2}{\nu f}} \frac{(1-i)}{2} \exp \left\{ (1+i) \sqrt{\frac{f}{2\nu}} z \right\} \quad [31]$$

Equation [31] describes a flow which at the sea surface $z = 0$ is directed at 45° to the right of the surface stress. The direction

of the flow spirals to the right as z becomes more negative. The net vertically integrated transport can be determined by integrating eqns [25] and [26] and applying the boundary conditions (eqn [27]). The result is

$$U = \int_{-\alpha}^0 u dz = 0 \quad V = \int_{-\alpha}^0 v dz = \frac{-\tau_x^0}{f} \quad [32]$$

If a nonzero stress in the y direction, τ_y^0 , had been specified as well, there would be obtained

$$U = \frac{\tau_y^0}{f} \quad V = -\frac{\tau_x^0}{f} \quad [33]$$

So the net transport in the frictional boundary layer is 90° to the right of the wind stress in the Northern Hemisphere. In the Southern Hemisphere, the transports are 90° to the left of the wind stress, and surface currents 45° to the left.

Since $f = 2\Omega \sin \theta$ vanishes at the equator, there is an equatorial transition from Northern to Southern Hemisphere behavior. All the examples discussed here apply to regions away from the equator. In the tropics, other terms become important in the equations describing the motion.

Critical Layers

P Haynes, University of Cambridge, Cambridge, UK

Synopsis

The terms critical line (or critical level) and critical layer, for small-amplitude waves propagating on a shear flow, are defined. At the critical line the simplest linear steady dissipationless theory for waves breaks down and must be resolved by adding other physical processes, such as unsteadiness, nonlinearity, or dissipation in a critical-layer region, which is a finite neighborhood of the critical line. The critical layer for Rossby waves is discussed in detail, highlighting the fact that the behavior within the critical layer affects the waves outside it, in particular determining whether or not the critical layer acts as an absorber, reflector, or overreflector to incident waves. In the case of a nonlinear critical layer, where dissipation can be largely neglected, this effect changes in time, so that the critical layer evolves from an absorbing state to a reflecting state, to an overreflecting state and then oscillates between weak overreflection and weak absorption, tending to a perfectly reflecting state. The behavior seen in the Rossby-wave nonlinear critical layer serves as a paradigm for the more general phenomenon of wave breaking, both with respect to the rearrangement of potential vorticity in the wave-breaking region and to the effect on neighboring wave-propagation regions. The corresponding behavior for internal-gravity waves is also discussed, which is more complicated than for Rossby waves, since there is wave propagation within the critical layer itself, so that the critical layer dynamics is a combination of wave propagation and nonlinear or dissipative behavior.

Introduction

Theoretical models of waves in the atmosphere naturally require consideration of propagation on a background state that is a shear flow. One example is that of Rossby waves (or planetary waves) propagating from the extratropical troposphere into the stratosphere. The background state is here the longitudinally averaged flow, which may include westerly winds increasing in strength with height (e.g., in the winter) or westerly winds at lower levels changing to easterly winds at upper levels (e.g., in the summer). Another example is that of small-scale internal-gravity waves excited by a mountain propagating upward through a large-scale flow that changes strength (and perhaps direction) with height.

Suppose that the background flow (i.e., the flow in the absence of the waves) is in the x -direction with speed U that is a function of a second space coordinate y and that the waves have a well-defined phase speed c in the x -direction. Then a location where $U(y) = c$, i.e., the flow speed matches the phase speed, is a line parallel to the x -axis and at a fixed value of y , called a *critical line*. Where the second space coordinate is height, the equivalent term *critical level* is often used. If the speed U was a function of two space coordinates y and z then the location $U(y, z) = 0$ would define a *critical surface*.

Simple theories for the structure of waves are often based on the assumptions that the waves are steadily propagating, that dissipative or diabatic processes such as friction or radiative transfer may be neglected, and that the waves are small-amplitude, so that terms in the equations of motion that are nonlinear in wave quantities may be neglected. These theories lead to a straightforward differential or partial differential equation that describes the spatial structure of the waves. The importance of the critical line is that it is a location where these differential equations are singular, in other words the solutions imply that some physical quantity becomes infinite.

As in many physical contexts, the appearance of singular behavior in a mathematical model implies that the

simplifications that lead to that model cannot be justified and that some physical process that was neglected must be retained. To remove the critical-line singularity one of the neglected processes mentioned above must therefore be included (however weak such processes might have been estimated to be). The neglected process will be essential only in a small, but finite, region around the critical line and may still be negligible elsewhere. This small but finite region is named the *critical layer*.

The Rossby-Wave Critical Layer

A Simple Model

One of the simplest examples of the critical-line singularity and its resolution in a finite critical layer arises in a two-dimensional model of Rossby-wave propagation on a β -plane (a mathematical device to include the effect of the variation of Coriolis parameter with latitude). Two-dimensional Cartesian coordinates (x, y) may be used, with x measured in the eastward direction and y measured in the northward direction. The corresponding velocity components are taken to be (u, v) . The assumption of incompressibility implies that the velocity components may be expressed in terms of a stream function $\psi(x, y, t)$ (with t time) where $u = -\partial\psi/\partial y$ and $v = \partial\psi/\partial x$.

The governing equation is based on the fact that, in the absence of dissipation, the absolute vorticity, which is the sum of the relative vorticity, $\zeta = (\partial v/\partial x) - (\partial u/\partial y) = \nabla^2\psi$, and the planetary vorticity, βy , is conserved following the fluid motion. β is a constant and in an Earth-like atmosphere is positive. It is convenient to include linear damping of vorticity in the model as a simple representation of a dissipative process. The governing equation then becomes

$$\left(\frac{\partial}{\partial t} + u\frac{\partial}{\partial x} + v\frac{\partial}{\partial y}\right)(\zeta + \beta y) = -\alpha\zeta \quad [1]$$

where α is the damping rate. (Another possibility for a dissipative process would be diffusion of vorticity. Neither linear

damping nor diffusion is likely to be realistic representations of dissipative processes in the real atmosphere, but either serves as a convenient example that captures the basic effect of dissipation in the critical layer.)

It is assumed that in the absence of waves the flow is in the x -direction with speed $U(y)$. Waves are superimposed on this flow giving a contribution $\psi'(x, y, t)$ to the stream function. Then the eqn [1] may be written in terms of ψ' as

$$\begin{aligned} \nabla^2 \psi'_t + U(y) \nabla^2 \psi'_x + [\beta - U''(y)] \psi'_x \\ = -\alpha \nabla^2 \psi' - u' \frac{\partial \nabla^2 \psi'}{\partial x} - v' \frac{\partial \nabla^2 \psi'}{\partial y} \end{aligned} \quad [2]$$

where $u' = -\partial \psi' / \partial y$ and $v' = -\partial \psi' / \partial x$ are the wave velocity components.

If the damping is weak then it is reasonable to neglect the first term on the right-hand side. If the waves are of small-amplitude then it is reasonable to neglect the second and third terms on the right-hand side, which are quadratic in wave quantities. Since the resulting equations are linear and contain no explicit x -dependence it is possible to consider waves with different wavelengths in the x -direction as independent.

Consider one such wave, with x -wavenumber k (i.e., wavelength $2\pi/k$ in the x -direction), assumed to be steadily propagating in the x -direction with phase speed c . It follows that the stream function for this wave may be written in the form $\psi'(x, y, t) = \text{Re}[\hat{\psi}(y)e^{ik(x-ct)}]$, where $\hat{\psi}(y)$ is a (complex) function of y . Substituting into eqn [2] and neglecting terms on the right-hand side gives the ordinary differential equation

$$\hat{\psi}'' + \left(\frac{\beta - U''(y)}{U(y) - c} - k^2 \right) \hat{\psi} = 0 \quad [3]$$

This equation is known as the Rayleigh–Kuo equation and, depending on context, determines the stability of the shear flow $U(y)$ in a problem where c is an eigenvalue, or when c is determined by forcing, which may be included in the problem by an extra term on the right-hand side of eqn [3] or by a boundary condition, describes through the function $\hat{\psi}(y)$ the structure of the forced disturbances. The focus here is on a steady forced problem, where c is given and real.

The appearance of the factor $[U(y) - c]^{-1}$ in part of the coefficient of $\hat{\psi}$ indicates that the equation has a singular point at values of y such that $U(y) = c$, i.e., where the phase speed matches the flow speed. These locations are the critical lines. If $U(y)$ is an increasing or decreasing function of y then there is at most one critical line. If $U(y)$ has a turning point (as would be the case for a jetlike flow, for example) then there may be more than one critical line.

Consider the solution near a critical line at $y = y_c$. The nature of eqn [3] is such that whilst $\hat{\psi}(y)$ (proportional to the velocity in the y -direction) is finite and continuous in the neighborhood of the critical line, $\hat{\psi}''(y)$ (representing part of the vorticity) is proportional to $(y - y_c)^{-1}$ and $\psi'(y)$ (representing the velocity in the x -direction) is proportional to $\log |y - y_c|$, i.e., both are singular. This is clearly unphysical, but what is more problematic, in a way, is that the singularity in $\hat{\psi}'(y)$ implies that there is no unique way to match solutions of eqn [3] across $y = y_c$. In particular the jump in $\hat{\psi}'(y)$, corresponding to the jump in u' , across $y = y_c$ remains unknown. It follows there is no unique solution in the whole flow domain for the

function $\hat{\psi}(y)$. The critical line singularity must therefore be resolved not only to remove the local singular behavior in certain physical quantities but also to determine the structure of the waves over the whole flow.

Absorption–Reflection

To note the implications of the critical layer for the waves elsewhere in the flow it is useful to focus on the following geometry, shown in Figure 1. Assume that the waves are forced at some large positive value of y , with phase speed $c = 0$, i.e., the waves are stationary. Assume also that the flow speed $U(y)$ is positive in $y > 0$ and negative in $y < 0$, so that the waves have a critical line at $y = 0$ and that the curvature term $U''(y)$ is not too large (so that $\beta - U''(y)$ is positive). The eqn [3] predicts that the function $\hat{\psi}(y)$ is oscillatory in $y > 0$, implying that there are propagating waves (as expected from the basic properties of Rossby waves). In $y < 0$, on the other hand, the function $\hat{\psi}(y)$ is exponentially increasing or decreasing with y and physical considerations require that $\hat{\psi}(y)$ decreases as y decreases, representing evanescent waves. One feature of the solution that is naturally of interest is the relative amount of northward- and southward-propagating waves in the region between the wave forcing and the critical layer. This measures the absorption–reflection behavior of the critical layer. If the critical layer acted as an absorber of waves then the region between the forcing and the critical line would contain only waves propagating southward. If it acted as a reflector of waves then there would be some contribution to the solution in this region from waves propagating northwards. The reflection could be partial or perfect. Indeed there could in principle be over-reflection, which would be associated with a greater proportion of northward-propagating than southward-propagating waves, implying that the critical layer was actively emitting waves.

A useful quantitative measure of the wave propagation is the momentum flux, $\overline{u'v'}$, where $\overline{(\cdot)}$ indicates an average in the x -direction (keeping y and t constant). $\overline{u'v'}$ indicates the correlation between the two velocity components and the basic properties of Rossby waves imply $\overline{u'v'} > 0$ for southward-propagating waves and $\overline{u'v'} < 0$ for northward-propagating waves. It follows from eqn [3] that $\overline{u'v'}$ is constant in $y > 0$, except at the critical line at $y = 0$. The evanescence of the waves in $y < 0$ implies that $\overline{u'v'} = 0$ there. However, the value of $\overline{u'v'}$ cannot be determined from eqn [3] alone. Instead the critical line must be resolved into a finite critical layer to allow the jump in $\overline{u'v'}$ across the layer, denoted by $[\overline{u'v'}]_+^+$, and hence the value of $\overline{u'v'}$ in $y > 0$, to be evaluated.

The continuity of $\hat{\psi}(y)$ across the critical line singularity suggests that, when the critical line is resolved into a thin critical layer, ψ' and hence $v' = \partial \psi' / \partial x$ will vary only weakly across the critical layer. In addition, y -derivatives within the critical layer will generally be much larger than x -derivatives (because the layer is thin), implying that $\zeta' \approx -\partial u' / \partial y$. Putting these pieces of information together, it follows that

$$[u']_+^+ = \int \zeta' dy \text{ and } \overline{u'v'} \text{ (in } y > 0) = [\overline{u'v'}]_+^+ = \int \overline{\zeta'v'} dy \quad [4]$$

where $[u']_+^+$ denotes the jump in u' across the critical layer, the integrals are taken across the critical layer, and v' may be taken as constant within the second integral. The first equality is the

Figure 1 Schematic diagram of Rossby-wave propagation on a shear flow $U(y)$ with a critical line. The flow is positive (i.e., eastward) in $y > 0$ (upper portion of the diagram) and negative (i.e., westward) in $y < 0$ (lower portion of the diagram). The waves are forced, with zero phase speed in x -direction, in $y > 0$ and propagate toward $y = 0$. In $y < 0$ the waves are evanescent (i.e., nonpropagating and decaying as y becomes more negative). The critical line is at $y = 0$, where $U(y) = 0$. In the neighborhood of $y = 0$ the streamlines are closed and form a Kelvin's cat's eye pattern. The width of the closed-streamline region, which increases as the wave amplitude increases, defines the width of the nonlinear critical layer. If dissipation were strong enough then dissipative effects would dominate over a relatively broad region near $y = 0$ and the closed streamlines would essentially be irrelevant to the dynamics. (The critical layer would then be linear and dissipative, rather than nonlinear.) There may be some reflected wave in $y > 0$, but the amount of reflection can be determined only by considering the detailed dynamics of the critical layer.

missing matching condition across the critical layer. The second shows that the critical layer acts as a net absorber of waves when there is (in a y -integrated sense) negative correlation between ζ' and v' in the critical layer, as a perfect reflector when there is zero correlation and as a net emitter (i.e., an over-reflector) when there is positive correlation.

To summarize, the nonuniqueness in the solution of eqn [3] left by the critical-line singularity leaves the absorption-reflection behavior of the critical layer uncertain. Only by determining the correlation between v' and ζ' in the critical layer is it possible to determine the precise absorption-reflection properties.

The Dynamics of the Critical Layer

The dynamical balance in the critical layer depends on the parameters of the problem. Consider in turn the processes that have been neglected in arriving at eqn [3]. Firstly it has been assumed that the waves are steadily propagating (i.e., that their amplitude is not changing with time). It is possible to analyze the nondissipative, linearized equations (eqn [2] with the right-hand side set to zero) without making this assumption and show that the singular behavior predicted by eqn [3] develops with time. For example, both the vorticity ζ' and the x -component of velocity u' are predicted to increase without bound. The time-dependent analysis shows that the terms neglected in going from eqns [2] to [3] inevitably become

important at large times, however small they might have first appeared.

Secondly, consider the dissipative term $-\alpha \nabla^2 \psi'$ in eqn [2]. This may be compared with the advection term $U(y) \partial \nabla^2 \psi' / \partial x$. The relative sizes of these terms, near to $y = 0$, may be estimated as $\alpha / k U'(0) y$ and it follows that the dissipative term cannot be neglected in a region of size $\delta_\alpha = \alpha / [k U'(0)]$. This is (potentially) the thickness of the dissipative critical layer.

Finally, consider the nonlinear term. It turns out that the most important part is $v' \partial \nabla^2 \psi' / \partial y$. If this is to balance $U(y) \partial \nabla^2 \psi' / \partial x \approx U'(0) y \partial \nabla^2 \psi' / \partial x$ in a thin region of thickness δ_{NL} , then $(v' / \delta_{NL} \approx k U'(0) \delta_{NL})$, i.e., $\delta_{NL} \sim [v' / k U'(0)]^{1/2}$. This is (potentially) the thickness of the nonlinear critical layer.

Whether nonlinearity or dissipation is dominant in the critical layer depends on the relative size of $\delta_{NL} / \delta_\alpha = [k v' U'(0)^{1/2} / \alpha]$. If $\delta_{NL} / \delta_\alpha \ll 1$ then the critical-layer dynamics are dominated by dissipation and the critical layer thickness is δ_α . If $\delta_{NL} / \delta_\alpha \gg 1$ then the critical-layer dynamics are dominated by nonlinear processes and the critical layer thickness is δ_{NL} . In the case of Rossby waves in the real atmosphere, wave amplitudes are relatively large and dissipation is relatively weak, so that the nonlinear dynamics are the most relevant.

The fully nonlinear equations state that $\zeta + \beta y$ is conserved following the flow (which is in turn determined by the ζ field). If the critical layer is thin, i.e., δ_{NL} is small, there is a simplification because the flow may be approximated by the superposition of the basic flow $U(y) \approx U'(0) y$ and the y -component

of the disturbance velocity field, which is simply a function of x , because of the continuity of ψ' across the critical layer. This superposition gives a flow whose streamlines form a pattern known as Kelvin's cat's eyes, with closed streamlines near $y = 0$ (see Figure 1). The dynamics of the nonlinear critical layer is therefore that fluid particles are advected around these streamlines, conserving their values of $\zeta + \beta y$. The rearrangement of the $\zeta + \beta y$ field changes the ζ' field, thereby changing $[u']_+^+$ and hence the structure of the waves outside the critical layer. Furthermore there is a corresponding change in the correlation between v' and ζ' , which determines the absorption–reflection properties.

A schematic diagram of the evolution of the vorticity field in a simple nonlinear critical layer is presented in Figure 2 and the absorption–reflection properties deduced. At early times v' and ζ' are anticorrelated and the critical layer acts as an absorber. If there is strong dissipation then the vorticity in the center of the critical layer is essentially frozen in its early time configuration and the critical layer continues to act as an absorber at later times. (Detailed calculation shows that in this early time/dissipative regime, the absorption is effectively perfect.) However if dissipation is weak then the advective rearrangement continues and, after about half a turn-round time for the closed-streamline flow, the ζ' field in the center of the critical layer (which gives the major contribution to the integral) is such that there is no y -integrated correlation with the v' field, i.e., the critical layer acts as a perfect reflector. According to this particular model, the advective rearrangement continues to give a positive correlation between v' and ζ' and hence overreflection and the critical layer subsequently oscillates between a weakly absorbing and weakly overreflecting state, converging to a state of perfect reflection at large times.

The precise details of the evolution depend on the particular flow configuration. However, a general description of absorption–reflection behavior can be formulated by considering $-\overline{u'v'}$ as the flux (in the y -direction) of wave activity (i.e., a quantity that is positive when waves are present and zero when they are not). In the early time absorbing stage wave activity builds up in the critical layer. As the reflecting stage approaches, the rate of buildup decreases to zero and in the overreflecting stage the critical layer reemits some of its wave activity. If there is dissipation then the flux of wave activity into the critical layer may be balanced by local dissipation of wave activity and an absorbing state may persist. However, for the critical layer to continue to act as an absorber without dissipation, then the amount of wave activity in the critical layer must continue to increase. The total amount of wave activity in the critical layer may be shown to depend on the thickness of the region over which the vorticity field has been rearranged (i.e., the thickness of the critical layer). If this thickness is finite then there is an upper bound to the total amount of wave activity that can be stored there and it is therefore not possible to sustain absorption. In such a case the long-time average of the flux of wave activity must approach zero and one can therefore say that the long-time average behavior is perfect reflection. The only way that absorption could be sustained in the long-term would be if the thickness of the critical layer systematically increased in size.

A complementary viewpoint comes from considering $\overline{u'v'}$ as a momentum flux. In the absorbing stage $[\overline{u'v'}]_+^+$ is positive,

implying that there is a negative force exerted on the x -averaged flow in the critical layer. The time-averaged perfect reflection in the case where dissipation is zero translates into no time-averaged x -average force exerted on the flow in the critical layer. (If there was such a force, then the critical line, and hence the critical layer, would move closer and closer to the wave source.) Sustained absorption where there is dissipation translates into a nonzero time-averaged x -average force exerted on the flow in the critical layer, with this force being balanced by forces provided by dissipative processes (i.e., by the linear vorticity damping in the model described above).

The critical layer theory makes clear the nature of the two-way interaction between the wave propagation region outside the critical layer, and the flow in the critical layer itself. The waves outside the critical layer directly determine the flow pattern inside it (because of the continuity of v' across the critical layer). However, inside the critical layer the flow changes the vorticity field and hence the jump in u' across the critical layer, thereby changing the waves outside it. It is important to note that there is no wave propagation within the critical layer itself. The dynamics is simply that of vorticity advection by a simple cat's eye flow whose structure is determined by the waves outside the critical layer. It is not the case that waves can be said to propagate into the critical layer and are reflected by the structure of the flow profile that they encounter there.

Wave Breaking

The behavior seen in the nonlinear critical layer for δ_{NL} small may be interpreted as an example of the breaking of Rossby waves. By 'breaking' it is meant that the material contours or surfaces that would, in wave propagation, be reversibly undulated, are strongly and irreversibly deformed. The most familiar example of wave breaking occurs for surface waves. There the wave dynamics is associated with the undulation of the ocean surface. Waves might be forced in one region (e.g., by a storm), and propagate through large distances. The presence of the waves in this propagation stage is associated with distortion of the ocean surface, but the distortion is weak and reversible. As the waves enter shallow water in a coastal region the distortion of the ocean surface becomes stronger and, ultimately, complex and irreversible and the flow will become three-dimensionally turbulent.

Rossby-wave propagation involves the reversible distortion of contours of potential vorticity (absolute vorticity in the simple two-dimensional context discussed above). In the critical layer region the distortion of these contours is strong and irreversible and the waves may be said to be breaking. Indeed in many cases the flow in the critical layer may be shown to involve a sort of turbulence (quasi-geostrophic or two-dimensional), but this is not essential for the behavior to be described as breaking. As in the surface-wave case, where the breaking may allow the waves to drive systematic long-shore currents, the breaking of Rossby waves allows a systematic force to be exerted by the waves.

Implications for the Atmosphere

In the nonlinear Rossby-wave critical layer described above there is a clear division (described by simplified mathematical

Figure 2 Evolution of vorticity field in the nonlinear critical layer. The panels show an expanded view of the vorticity field in the closed-streamline region indicated in [Figure 1](#). Note that this region may be very thin in the y -direction if the wave amplitude is small. Thick dotted curves are the bounding closed streamlines. Thick solid curves are contours of absolute vorticity $\zeta + \beta y$. Thin curves are contours of wave relative vorticity ζ' , with solid curves indicating positive values and dashed curves indicating negative values. Three panels show (a) absorbing stage, where y -velocity v' is negatively correlated with ζ' , (b) reflecting stage, where correlation between v' and ζ' is close to zero, and (c) overreflecting stage, where v' is positively correlated with ζ' .

equations that may be derived by a formal approximation procedure) between the broad region outside the critical layer where the dynamics is wavelike and the thin critical layer itself where the dynamics is a strong advective rearrangement of the potential vorticity or absolute vorticity field, which might be called wave breaking. In the real atmosphere the wave amplitudes are very large and the formal estimate δ_{NL} of the nonlinear critical layer thickness is generally as large as the other length scales in the problem. The same simplified mathematical equations do not hold precisely. Nonetheless observations and numerical models show clearly that there are regions of wave propagation and regions of wave breaking and that these exist side-by-side. There are at least two important examples. One is in the winter stratosphere, where planetary-scale Rossby waves propagate up from the troposphere, distort and shift the polar-night vortex, and break in what is now called the stratospheric ‘surf zone’ (which covers a large region of the midlatitudes and subtropics). The stirring of potential vorticity in the surf zone leads to weak large-scale gradients in the interior of the surf zone and corresponding strong gradients at its poleward edge, which is the boundary of the polar vortex. These strong potential vorticity gradients act as a kind of wave guide for upward propagation of Rossby waves. A second is in the upper troposphere and lower stratosphere, where synoptic-scale baroclinic eddies lead to a wavelike distortion of the subtropical jet and to wave-breaking regions on the poleward and equatorward sides of the jet. Again the effect on potential vorticity (PV) gradients is to lead to a kind of wave guide for tropospheric Rossby waves.

In these examples nonlinear critical layer theory provides quantitative guidance as to how the different regions interact. For example, it indicates that the wave-breaking regions may be considered to absorb, reflect, or emit wave activity and that the waves may have a systematic effect on the flow in the wave-breaking region.

In the last 10 years or so Rossby-wave critical layer ideas have also been applied to hurricane dynamics. For example, the role of nonaxisymmetric Rossby-wave disturbances to a hurricane in promoting hurricane intensification have been described in terms of the propagation of such disturbances and their subsequent dissipation in a critical layer. In a separate line of argument, the nonlinear critical layer of a subtropical Rossby wave has been interpreted as a preferred location for hurricane vortex development, with one stage of the development being a period of copropagation (in longitude) of the preexisting wave and the growing vortex.

Internal-Gravity Wave Critical Layers

Description

Critical lines and critical layers arise generically in any problem of wave propagation in a fluid. Another example that is particularly important for the atmosphere is that of internal-gravity waves. This has some important differences from the Rossby-wave case.

Consider the propagation of internal-gravity waves on a background state that has stable stratification with buoyancy frequency $N(z)$ and flow in the x -direction with speed $U(z)$, where z is height. Assuming that the flow is incompressible (which is not necessarily defensible for many atmospheric

gravity waves, but the model serves to illustrate important points that continue over to the compressible case) it may be shown that the analogue of eqn [3] is

$$\hat{\psi}'' + \left\{ \frac{N^2(z)}{[U(z) - c]^2} - \frac{U''(z)}{U(z) - c} - k^2 \right\} \hat{\psi} = 0 \quad [5]$$

This equation is known as the Taylor–Goldstein equation and, as is the case for eqn [3] for Rossby waves, depending on the context determines the stability of density-stratified shear flows or the structure of waves propagating on such flows. Again the critical line singularity at $U(z) = c$ is manifested by the inverse powers of $U(z) - c$ appearing in the expression multiplying $\hat{\psi}$. There is an important difference from eqn [3] in that one of the expressions contains the factor of $[U(z) - c]^{-2}$. This means that the behavior of solutions near the critical-line singularity is quite different from the Rossby-wave case. In fact, provided that the local Richardson number $Ri = N^2(z)/U'(z)^2 > 1/4$ (which is precisely the condition required for the flow to be stable) the function $\hat{\psi}(z)$ oscillates rapidly in z near to the critical line and the oscillations become infinitely rapid as the critical line is approached. Indeed there are infinitely many oscillations before the critical line is reached. These oscillations are a manifestation of the rapid shrinking of the vertical wavelength of the wave as the critical line is approached, due to the tilting of the wave by the shear. An analogous shrinking of the wavelength occurs in the Rossby-wave case, but there are only a finite number of oscillations before the critical line is reached – a subtle and important difference between this and the internal-gravity wave case. The reason for the difference is that in the internal-gravity wave case decrease in wavelength gives a stronger decrease in the group velocity (i.e., the propagation velocity for wave packets). Indeed in the Rossby-wave case the idea of group velocity is simply not at all useful in the neighborhood of the critical line, whereas in the internal-gravity wave case it is. (The systematic reduction of the group velocity as the internal-gravity wave approaches a critical line may be recognized as an example of a more general ‘wave-capture’ phenomenon that occurs in a much wider class of background flows, where the deformation by the background flow acts to shrink the wavelength and hence reduce the group velocity.)

For the internal-gravity wave case, as for the Rossby-wave case, it is natural to consider whether the critical layer acts as an absorber, reflector, or overreflector of waves (or indeed as a transmitter, since the different form of the equation means that wave propagation can occur on either side of the critical line) and how this depends on the physical processes acting in the critical layer (e.g., the relative strengths of dissipation and nonlinearity). The arguments just given concerning group velocity, with waves stagnating as they approach the critical line, suggest absorption, at least if dissipation is dominant, since the decrease in group velocity as the critical line is approached means that there is infinite time for the dissipation to act. Indeed the wave will, in practice, dissipate before the critical line is reached (and indeed the thickness of the dissipative critical layer may be defined as the distance to the critical line at which the dissipation occurs).

This heuristic prediction for absorption based on group velocity was refined by the detailed calculations of Booker and

Bretherton in 1967, who considered eqn [5] in the case when the buoyancy frequency N and the vertical shear $U'(z)$ were both constant, so that the only parameter in the (nondissipative) problem is Ri . Their analysis did not require any particular assumption about dissipation, but implicitly assumes that dissipation is present. They showed that a fraction $\exp\left\{-2\pi\left(Ri - \frac{1}{4}\right)^{1/2}\right\}$ of an incident wave would be transmitted across the critical layer, with the remainder absorbed. Thus, according to this linear analysis, the critical layer is a perfect absorber in the limit of large Ri . However, if wave amplitudes are sufficiently large compared to dissipative processes, then nonlinear terms in the equations may become important before dissipation occurs and, again, before the critical line is reached. The distance to the critical line defines the thickness of the nonlinear critical layer. Here the situation is more complicated than in the Rossby-wave case. For example, it is not possible to argue that the velocity component in the z -direction (analogous to v' in the Rossby-wave case) is continuous across the nonlinear critical layer (and therefore independent of z within the critical layer). If governing equations for the nonlinear critical layer are derived, they are essentially the full nonlinear governing dynamical equations, with a slight simplification because the structure is very thin in the z -direction. The critical-layer dynamics is therefore a complex juxtaposition of wave propagation and nonlinearity.

Furthermore if nonlinearity is important it is also almost inevitable that there will be the potential for gravitational instability and therefore, in reality, breakdown of the flow into complex three-dimensional turbulence. For this reason, while there have been some formal asymptotic studies of nonlinear internal-gravity wave critical layers, the behavior that is most likely to be relevant in the real atmosphere is better investigated using full three-dimensional numerical simulation. Evidence from such simulations is that some nonlinear reflection effect is possible, particularly when the local Richardson number is not too large.

Implications for the Atmosphere

Dissipation and breaking of internal-gravity waves as they approach critical lines is potentially an important process in the atmosphere, since it implies the possibility of wave-induced forces. Breaking may also be caused by the decrease of density with height, which leads to a corresponding increase in wave amplitudes. However, there is little doubt that breaking at (or more strictly near) critical lines also plays a major role. For example, the mechanism for the equatorial quasi-biennial oscillation in the stratosphere requires selective filtering, breaking, and dissipation of waves (depending on their horizontal phase speed) by the background flow. Such waves

are believed to arise primarily from convection in the tropical troposphere (on a whole range of different scales). Observations confirm the expected relation between the phase speed of the waves observed at a particular height and the background flow at lower levels, through which they would have propagated.

Critical-line/critical-layer behavior is an important ingredient of gravity-wave parametrizations, which seek to represent the effects (primarily the wave-induced forces) of small-scale gravity waves in global-scale numerical models. Such parametrization is essential for useful simulation of the stratosphere and mesosphere. One very simple parametrization would be that, for a spectrum of upward-propagating gravity waves, each component of the spectrum dissipates at its critical line and therefore gives rise to a force at that location. In practice, some kind of breaking criterion is applied so that waves break before the critical line is reached. Almost all current parametrizations assume the equivalent of critical-layer absorption. If critical-layer reflection had to be taken into account then it would greatly increase the complexity of the parametrization problem.

Introduction

Hamiltonian dynamics describes the evolution of conservative physical systems. Originally developed as a generalization of Newtonian mechanics, describing gravitationally driven motion from the simple pendulum to celestial mechanics, it also applies to such diverse areas of physics as quantum mechanics, quantum field theory, statistical mechanics, electromagnetism, and optics — in short, to any physical system for which dissipation is negligible. Dynamical meteorology consists of the fundamental laws of physics, including Newton's second law. For many purposes, diabatic and viscous processes can be neglected and the equations are then conservative. (For example, in idealized modeling studies, dissipation is often only present for numerical reasons and is kept as small as possible.) In such cases dynamical meteorology obeys Hamiltonian dynamics. Even when nonconservative processes are not negligible, it often turns out that separate analysis of the conservative dynamics, which fully describes the nonlinear interactions, is essential for an understanding of the complete system, and the Hamiltonian description can play a useful role in this respect. Energy budgets and momentum transfer by waves are but two examples.

Hamiltonian dynamics is often associated with conservation of energy, but it is in fact much more than that. Hamiltonian dynamical systems possess a mathematical structure that ensures some remarkable properties. Perhaps the most important is the connection between symmetries and conservation laws known as Noether's theorem. Well-known examples are the fact that conservation of energy is linked to symmetry in time, and conservation of momentum to symmetry in space. Less well-known is the fact that material conservation of potential vorticity, so crucial to the theory of dynamical meteorology, is also connected to a symmetry by Noether's theorem, but to a symmetry that is invisible in the Eulerian formulation of the governing equations. It turns out that one can exploit the underlying Hamiltonian structure of a system through the relevant conservation laws even if the explicit form of that structure is not known, which is useful for applications. As is shown in detail below, symmetry-based conservation laws provide a general theory of available potential energy, and show why it is that Rossby waves carry negative zonal momentum, thereby explaining both the maintenance of the westerlies and the stratospheric Brewer–Dobson circulation. Such laws also provide a powerful way of deriving stability criteria.

Dynamical meteorologists use a variety of theoretical models, ranging from the fully compressible equations through the hydrostatic primitive, Boussinesq, and quasi-geostrophic equations to the barotropic equations. With such a zoo of models, it is crucial to know the extent to which theories developed for one model carry over to another.

Hamiltonian dynamics provides this unifying framework. All the models just mentioned are in fact Hamiltonian, and models can be grouped into families according to their Hamiltonian structure. In this way it becomes immediately apparent, for example, that the Charney–Stern stability theorem for baroclinic quasi-geostrophic flow is the counterpart to Rayleigh's inflection-point theorem for barotropic flow, and that an analogous stability theorem will exist for any balanced model having a similar Hamiltonian structure, no matter what the definition is of the potential vorticity. Thus, it is precisely through its abstract character that Hamiltonian dynamics has many powerful applications in theoretical dynamical meteorology.

Canonical and Noncanonical Dynamics

In classical mechanics, canonical Hamiltonian dynamical systems are those described by Hamilton's equation (eqns [1]).

$$\frac{dq_i}{dt} = \frac{\partial \mathcal{H}}{\partial p_i}, \quad \frac{dp_i}{dt} = -\frac{\partial \mathcal{H}}{\partial q_i} \quad (i = 1, \dots, N) \quad [1]$$

$\mathcal{H}(\mathbf{q}, \mathbf{p})$ is the Hamiltonian function, $\mathbf{q} \equiv (q_1, \dots, q_N)$ are the generalized coordinates, and $\mathbf{p} \equiv (p_1, \dots, p_N)$ the generalized momenta. For so-called natural systems with $\mathcal{H} = (|\mathbf{p}|^2/2m) + U(\mathbf{q})$, where m is the mass and U the potential energy, eqns [1] immediately lead to eqn [2], which is Newton's second law for a conservative system.

$$m \frac{d^2 q_i}{dt^2} = -\frac{\partial U}{\partial q_i} \quad (i = 1, \dots, N) \quad [2]$$

Conservation of energy follows directly from eqns [1], for any $\mathcal{H}$, by the chain rule (repeated indices are summed):

$$\frac{d\mathcal{H}}{dt} = \frac{\partial \mathcal{H}}{\partial q_i} \frac{dq_i}{dt} + \frac{\partial \mathcal{H}}{\partial p_i} \frac{dp_i}{dt} = \frac{\partial \mathcal{H}}{\partial q_i} \frac{\partial \mathcal{H}}{\partial p_i} - \frac{\partial \mathcal{H}}{\partial p_i} \frac{\partial \mathcal{H}}{\partial q_i} = 0 \quad [3]$$

Symplectic Formulation

The theory of canonical transformations suggests that there is nothing special about the qs and ps , and Hamilton's equations [1] can be written in the so-called symplectic form, eqn [4].

$$\frac{du_i}{dt} = J_{ij} \frac{\partial \mathcal{H}}{\partial u_j} \quad (i = 1, \dots, 2N) \quad [4]$$

In eqn [4], $\mathbf{u} = (q_1, \dots, q_N, p_1, \dots, p_N)$ and J is given by eqn [5], where I is the $N \times N$ identity matrix.

$$J = \begin{pmatrix} 0 & I \\ -I & 0 \end{pmatrix} \quad [5]$$

J has certain mathematical properties, including skew-symmetry. More generally, one can take those properties to be

the definition of Hamiltonian structure, with J not necessarily of the form of eqn [5]. The skew-symmetry of J nevertheless guarantees energy conservation (eqn [6]).

$$\frac{d\mathcal{H}}{dt} = \frac{\partial \mathcal{H}}{\partial u_i} \frac{du_i}{dt} = \frac{\partial \mathcal{H}}{\partial u_i} J_{ij} \frac{\partial \mathcal{H}}{\partial u_j} = 0 \quad [6]$$

There is an important distinction between systems with a nonsingular (or invertible) J , which can always be transformed into the canonical form of eqn [5], and those with a singular (or noninvertible) J . The latter, known as noncanonical systems, possess a special class of invariant functions known as Casimir invariants. These are the solutions of eqn [7] (for canonical systems the solutions are just constants).

$$J_{ij} \frac{\partial \mathcal{C}}{\partial u_j} = 0 \quad (i = 1, \dots, 2N) \quad [7]$$

That they are necessarily conserved in time then follows from the skew-symmetry of J (eqn [8]).

$$\frac{d\mathcal{C}}{dt} = \frac{\partial \mathcal{C}}{\partial u_i} \frac{du_i}{dt} = \frac{\partial \mathcal{C}}{\partial u_i} J_{ij} \frac{\partial \mathcal{H}}{\partial u_j} = -\frac{\partial \mathcal{H}}{\partial u_j} J_{ij} \frac{\partial \mathcal{C}}{\partial u_i} = 0 \quad [8]$$

The best-known example of a noncanonical Hamiltonian system is Euler's equations for rigid-body dynamics. Having an odd number of evolution equations (three in this case), the system is necessarily noncanonical because any skew-symmetric matrix of odd dimension must be singular. There is one Casimir invariant for Euler's equations, the total angular momentum.

Noether's Theorem

For a canonical system, if a particular generalized coordinate q_j does not appear in the Hamiltonian, then the Hamiltonian is invariant under changes in that coordinate; in other words, there is a coordinate symmetry. Translational and rotational symmetries are common examples. Hamilton's equations [1] then immediately imply that the corresponding generalized momentum is conserved: $dp_j/dt = 0$.

This connection between symmetries and conservation laws has a more general and far more powerful form. Given a function $\mathcal{F}(\mathbf{u})$, define $\delta_{\mathcal{F}} u_i = \varepsilon J_{ij}(\partial \mathcal{F} / \partial u_j)$, where ε is an infinitesimal parameter; $\delta_{\mathcal{F}} \mathbf{u}$ is called the infinitesimal variation in $\mathbf{u}$ generated by $\mathcal{F}$. (In the canonical case, $\delta_{\mathcal{F}} \mathbf{u}$ is an infinitesimal canonical transformation.) It then follows that the infinitesimal variation in $\mathcal{H}$ generated by $\mathcal{F}$ is given by eqn [9].

$$\delta_{\mathcal{F}} \mathcal{H} = \frac{\partial \mathcal{H}}{\partial u_i} \delta_{\mathcal{F}} u_i = \varepsilon \frac{\partial \mathcal{H}}{\partial u_i} J_{ij} \frac{\partial \mathcal{F}}{\partial u_j} \quad [9]$$

On the other hand, the time evolution of $\mathcal{F}$ is given by eqn [10].

$$\frac{d\mathcal{F}}{dt} = \frac{\partial \mathcal{F}}{\partial u_i} \frac{du_i}{dt} = \frac{\partial \mathcal{F}}{\partial u_i} J_{ij} \frac{\partial \mathcal{H}}{\partial u_j} \quad [10]$$

Using the skew-symmetry of J , eqns [9] and [10] then imply that $\delta_{\mathcal{F}} \mathcal{H} = 0$ if and only if $d\mathcal{F}/dt = 0$. This connects symmetries and conservation laws: the Hamiltonian is invariant under the variation generated by $\mathcal{F}$ (i.e., that variation represents a symmetry of the Hamiltonian) if and only if $\mathcal{F}$ is a conserved quantity. This result, known as Noether's theorem, is one of the central results of Hamiltonian dynamics

and underpins many of its applications to dynamical meteorology.

Casimir invariants are special because $\delta_{\mathcal{C}} \mathbf{u} = 0$. This suggests that they correspond to invisible symmetries. For example, in rigid-body dynamics the total angular momentum is a conserved quantity in any description of the motion. In the original canonical description it corresponds to the rotational symmetry of the dynamics, but in Euler's equations, where angles have been eliminated, it enters as a Casimir because the underlying physical symmetry is no longer explicit.

Barotropic Dynamics

In what sense are the models of dynamical meteorology Hamiltonian? Consider what is probably the simplest such model, the barotropic vorticity equation (eqn [11]), which describes two-dimensional, nondivergent flow.

$$\frac{\partial \omega}{\partial t} = -\mathbf{v} \cdot \nabla \omega = -\partial(\psi, \omega) \quad [11]$$

Here $\omega(x, y, t) = \hat{\mathbf{z}} \cdot (\nabla \times \mathbf{v}) = \nabla^2 \psi$ is the vorticity, $\hat{\mathbf{z}}$ is the unit vector in the vertical direction, $\mathbf{v}(x, y, t) = \hat{\mathbf{z}} \times \nabla \psi$ is the horizontal velocity, $\psi(x, y, t)$ is the streamfunction, and $\partial(f, g) \equiv f_x g_y - f_y g_x$ is the two-dimensional Jacobian. The candidate Hamiltonian is the conserved energy of this system, which is just the kinetic energy. The obvious dynamical variable is the vorticity. In order to cast eqn [11] in the form of eqn [4], we need to regard every point (x, y) in space as indexing a degree of freedom analogous to the index i ; the sum over i then becomes an integral over space, functions become functionals, and partial derivatives become functional or variational derivatives. Thus we write eqn [12].

$$\begin{aligned} \delta \mathcal{H} &= \delta \iint \frac{1}{2} |\nabla \psi|^2 dx dy \\ &= \iint \nabla \psi \cdot \delta \nabla \psi dx dy \\ &= \iint \{ \nabla \cdot (\psi \delta \nabla \psi) - \psi \delta \omega \} dx dy \end{aligned} \quad [12]$$

Assuming for now that the boundary terms vanish, we identify the variational derivative as $\delta \mathcal{H} / \delta \omega = -\psi$. The need to integrate by parts reflects the fact that the effect of a vorticity perturbation on the kinetic energy density is nonlocal; thus, partial derivatives at fixed points in space make no sense and variational derivatives are essential. Equation [11] can now be cast in Hamiltonian form as eqn [13].

$$\frac{\partial \omega}{\partial t} = J \frac{\delta \mathcal{H}}{\delta \omega} \quad \text{where } J = -\partial(\omega, \cdot) \quad [13]$$

Note that J is now a differential operator rather than a matrix. It is evidently skew-symmetric: $\iint fg dx dy = -\iint gf dx dy$ (under suitable boundary conditions) for arbitrary functions f, g .

Conservation Laws

The form of J in eqn [13] is clearly singular: any function of ω inserted in the argument gives zero. These then represent

Casimir invariants of the system: functionals of the form [14], where $C(\cdot)$ is an arbitrary differentiable function, evidently satisfy $J(\delta \mathcal{C} / \delta \omega) = 0$.

$$\mathcal{C} = \iint C(\omega) dx dy \quad \text{with} \quad \frac{\delta \mathcal{C}}{\delta \omega} = C'(\omega) \quad [14]$$

The fact that such functionals are conserved in time corresponds to the material conservation of vorticity expressed by eqn [11].

To identify the momentum invariants, we need to apply Noether's theorem to the various spatial symmetries. Suppose that the domain is unbounded, with decay conditions at infinity, so that there is symmetry in all directions. The variation in ω corresponding to a translation by δx in the coordinate x is given by $\delta \omega = -(\partial \omega / \partial x) \delta x$. Setting $\varepsilon = \delta x$, we then need to solve for the momentum invariant $\mathcal{M}$ according to eqn [15].

$$-\varepsilon \frac{\partial \omega}{\partial x} = \delta_{\mathcal{M}} \omega = \varepsilon J \frac{\delta \mathcal{M}}{\delta \omega} = -\varepsilon \partial \left(\omega, \frac{\delta \mathcal{M}}{\delta \omega} \right) \quad [15]$$

To within the addition of a Casimir, the solution of eqn [15] is given by $\delta_{\mathcal{M}} \omega = \gamma$. Hence we may choose $\mathcal{M}$ as in eqn [16], where $\mathbf{v} = (u, v)$.

$$\begin{aligned} \mathcal{M} &= \iint \gamma \omega dx dy = \iint \gamma \left(\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} \right) dx dy \\ &= \iint u dx dy \end{aligned} \quad [16]$$

The first, elementary form of $\mathcal{M}$ given by eqn [16] is known as Kelvin's impulse. It represents the γ 'center-of-mass' of the vorticity distribution, and is in many ways the preferable form because it is local in ω . The final form, however, shows that the invariant $\mathcal{M}$ corresponding to symmetry in x is ultimately just the x -momentum, as expected.

The same argument applied to translation in the coordinate y yields eqn [17].

$$\mathcal{M} = - \iint x \omega dx dy = \iint v dx dy \quad [17]$$

Finally, rotational symmetry leads to eqn [18], where $\mathbf{r} \equiv (x, y)$ and $r = |\mathbf{r}|$, which is the angular momentum about the origin.

$$\mathcal{M} = - \iint \frac{1}{2} r^2 \omega dx dy = \iint \hat{\mathbf{z}} \cdot (\mathbf{r} \times \mathbf{v}) dx dy \quad [18]$$

The discussion has so far neglected any contribution from boundary terms. They are easily included. In the presence of rigid lateral boundaries, for a complete mathematical specification of the problem, eqn [11] must be supplemented with the conditions [19] on each connected portion of the boundary.

$$\mathbf{v} \cdot \hat{\mathbf{n}} = 0, \quad \frac{d}{dt} \oint \mathbf{v} \cdot d\mathbf{s} = 0 \quad [19]$$

Here $\hat{\mathbf{n}}$ is the outward-pointing normal, and $\mathbf{s}$ is the vector arc length along the boundary. The second of eqns [19] represents conservation of circulation, which follows from the underlying momentum equations but must be included as a separate condition in the vorticity formulation of the dynamics. Although the circulation integrals along each

connected portion of the boundary are constants in time, they are independent dynamical variables and are needed to determine $\mathbf{v}$ from ω . The Hamiltonian formulation of eqn [13] may easily be extended to include the circulation integrals in addition to ω as dynamical variables. The Casimir invariants then include functions of these circulation integrals. With regard to the momentum invariants, of course, the rigid boundaries must respect the same symmetries; a zonal channel flow with walls at constant y breaks the translational symmetry in y and the rotational symmetry, leaving only the zonal impulse of eqn [16] as an invariant. The final equality of eqn [16] is then no longer strictly true, but the impulse and momentum differ only by terms involving the circulations along the channel walls, which are Casimirs. Since symmetry-based invariants are only defined to within a Casimir in any case, the impulse and momentum are essentially equivalent.

A simplified model of barotropic dynamics is the point-vortex model, where the vorticity is concentrated in Dirac delta functions. The point-vortex model has been used to study two-dimensional turbulence and certain kinds of atmospheric flow structures. It also turns out to be Hamiltonian, and is in fact a canonical system: the Casimirs are built into the model as parameters through the choice of the point-vortex strengths.

Other Balanced Models

The barotropic vorticity equation has a mathematical structure that is analogous to that of many models of balanced, or potential-vorticity-driven, flow (see **Dynamical Meteorology: Balanced Flow**) and the results derived above extend in an obvious way to such systems. Inclusion of the beta effect means simply a change from ω to the potential vorticity $q = \omega + \beta y$. Since $\delta y = 0$ (recalling that the coordinate y is like an index), $\delta q = \delta \omega$ and eqns [11], [12], [13] and [14] go through unchanged with q in place of ω . However the beta effect breaks translational symmetry in y and rotational symmetry, leaving only the translational symmetry in x represented by the zonal impulse invariant of eqn [16]. Strictly speaking the latter should be written with q in place of ω , but the integrals differ by a constant and so represent the same invariant. Inclusion of topography is no more difficult; one simply includes an additional topographic term $h(x, y)$ in the definition of q . This will generally break all spatial symmetries, leaving only the energy $\mathcal{H}$ and Casimirs $\mathcal{C}$ as invariants. This illustrates a general and important point, namely, that symmetry-based invariants are fragile: a slight change in the conditions of the problem destroys their conservation properties. In contrast, the energy and the Casimirs are robust invariants (robust within the conservative context, of course) that survive such perturbations.

Stratification is most easily introduced in the context of the quasi-geostrophic (QG) model (see **Dynamical Meteorology: Quasigeostrophic Theory**). Layered QG models are completely trivial extensions of the barotropic system: their evolution is determined by the potential vorticity $q_i(x, y, t)$ in each layer i , governed by eqn [11] with q_i in place of ω , together with conservation of circulation along any rigid lateral boundaries that may be present. These are then the dynamical variables. The energy now includes available potential as well as kinetic energy, but, apart from some geometric factors

representing the layer depths, one still recovers $\delta\mathcal{H}/\delta q_i = -\psi_i$ in each layer as well as eqn [13] with q_i in place of ω . The various invariants follow in the obvious way with the spatial integrals summed over the different layers. The same considerations, incidentally, apply to layered non-QG ‘intermediate’ models that still have the form of eqn [11] – namely, nondivergent horizontal advection of the potential vorticity q_i within each layer, with the flow in each layer driven by the potential vorticity in all layers (as described by the particular definition of q_i).

With continuous stratification and with upper and lower boundaries (at $z = 1$ and $z = 0$, say), there is an additional effect. It is well known that the temperature distribution along the upper and lower boundaries is equivalent to potential vorticity (see **Dynamical Meteorology: Baroclinic Instability**), and independent evolution equations for these temperature distributions are required to fully specify the continuously stratified QG system, in addition to the equation for the interior potential vorticity (the latter being eqn [11], with q in place of ω , applied at every value of z ; thus, the advection of q remains purely horizontal). The Eady model is an extreme case where the interior potential vorticity is uniform and the flow is driven entirely by the temperature distributions on the upper and lower boundaries; the dynamical structures driven from each boundary are known as Eady edge waves. Since these temperature distributions also evolve according to eqn [11], with the QG temperature ψ_z in place of ω , it is not surprising that the same kind of Hamiltonian structure also applies to this model. The energy is given by eqn [20].

$$\mathcal{H} = \iiint \frac{\rho_s}{2} \left\{ |\nabla\psi|^2 + \frac{1}{S} \psi_z^2 \right\} dx dy dz \quad [20]$$

In eqn [20], the reference-state density $\rho_s(z)$ and stratification function $S(z) = N^2/f^2$ are both prescribed, with $N(z)$ the buoyancy frequency and f the Coriolis parameter, and where ∇ is still just the horizontal gradient operator. With the potential vorticity given by eqn [21], where f and β are constants, eqn [22] follows.

$$q(x, y, z, t) = \psi_{xx} + \psi_{yy} + \frac{1}{\rho_s} \left(\frac{\rho_s}{S} \psi_z \right)_z + f + \beta\gamma \quad [21]$$

$$\delta\mathcal{H} = \left[\iint \frac{\rho_s}{S} \psi \delta\psi_z dx dy \right]_{z=0}^{z=1} + \iiint \{ \nabla \cdot (\rho_s \psi \delta \nabla \psi) - \rho_s \psi \delta q \} dx dy dz \quad [22]$$

This is like eqn [12], but with an additional term involving the temperature variations $\delta\psi_z$ at the upper and lower boundaries. Including these as independent dynamical variables, in addition to q (and possibly also circulation terms), the governing equations can be cast in the symplectic form of eqn [13]. The Casimirs now involve integrals of arbitrary functions of the temperature on the upper and lower boundaries, in addition to integrals of arbitrary functions of potential vorticity in the interior (eqn [23]).

$$\mathcal{C} = \iiint C(q; z) dx dy dz + \iint C_0(\psi_z) dx dy \Big|_{z=0} + \iint C_1(\psi_z) dx dy \Big|_{z=1} \quad [23]$$

The momentum invariants similarly extend in obvious ways: for example, the zonal impulse invariant is given by eqn [24].

$$\mathcal{M} = \iiint \rho_s \gamma q dx dy dz + \iint \frac{\rho_s}{S} \gamma \psi_z dx dy \Big|_{z=0} - \iint \frac{\rho_s}{S} \gamma \psi_z dx dy \Big|_{z=1} \quad [24]$$

The semi-geostrophic (SG) model (see **Synoptic Meteorology: Frontogenesis**) is widely used in mesoscale dynamics because of its ability to represent realistic frontal structures. It turns out that the SG model can also be cast in the form of eqn [11], and hence in the symplectic form of eqn [13], provided the equations are written in isentropic–geostrophic coordinates. However, in these coordinates rigid boundaries appear to move in time. The SG equations, in contrast to the QG equations, make no geometrical distinction between horizontal and vertical boundaries – this is why they are also useful for the study of coastal dynamics in physical oceanography – and the same kind of independent dynamical degrees of freedom encountered in the QG system on upper and lower boundaries also appear on lateral boundaries. In the special case of channel walls, these degrees of freedom correspond to coastal Kelvin waves and are analogous in some respects to the Eady edge waves represented by both the QG and SG systems. They must be taken into account in the variational calculations, and enter into many of the resulting expressions.

Unbalanced Models

Balanced models are controlled by the advection of potential vorticity (perhaps augmented by the advection of isentropic surfaces on rigid boundaries), so for such models it is natural to seek a Hamiltonian description analogous to eqn [13]. However, models that include a representation of gravity waves or other high-frequency oscillations, called unbalanced models, do not fit within this framework. They necessarily have additional degrees of freedom. For such models, a description in terms of the velocity field is a more natural way to reflect the Hamiltonian structure. For example, the rotating shallow-water equations [25] with $\mathbf{v}(x, y, t) = (u, v)$ the horizontal velocity, $h(x, y, t)$ the fluid depth, g the gravitational acceleration, and with constant f , conserve the energy (eqn [26]).

$$\frac{\partial \mathbf{v}}{\partial t} + (f \hat{\mathbf{z}} + \nabla \times \mathbf{v}) \times \mathbf{v} + \nabla \left(\frac{1}{2} |\mathbf{v}|^2 \right) = -g \nabla h, \quad [25]$$

$$\frac{\partial h}{\partial t} + \nabla \cdot (h \mathbf{v}) = 0$$

$$\mathcal{H} = \iint \frac{1}{2} \{ h |\mathbf{v}|^2 + g h^2 \} dx dy \quad [26]$$

The dynamical variables are $\mathbf{v}$ and h , for which eqns [27] hold.

$$\frac{\delta \mathcal{H}}{\delta \mathbf{v}} = h \mathbf{v}, \quad \frac{\delta \mathcal{H}}{\delta h} = \frac{1}{2} |\mathbf{v}|^2 + g h \quad [27]$$

Note that no integration by parts is necessary in this case; this is characteristic of velocity-based representations of the dynamics. It can easily be verified that eqns [25] may be cast in the symplectic form $(\partial \mathbf{u} / \partial t) = J(\delta \mathcal{H} / \delta \mathbf{u})$ with $\mathbf{u} = (u, v, h)$ with J

given by eqn [28], where $q = (f + \hat{\mathbf{z}} \cdot \nabla \times \mathbf{v})/h$ is the potential vorticity of the shallow-water system.

$$J = \begin{pmatrix} 0 & q & -\partial_x \\ -q & 0 & -\partial_y \\ -\partial_x & -\partial_y & 0 \end{pmatrix} \quad [28]$$

The matrix (28) is evidently skew-symmetric; the signs on the derivative terms are indeed correct, since first-order differential operators are themselves skew-symmetric, as with the J in eqn [13]. The zonal (absolute) momentum invariant is given as expected by eqn [29], for which it is easy to verify that $J(\delta \mathcal{M}/\delta \mathbf{u}) = -\partial \mathbf{u}/\partial x$ in line with Noether's theorem, and the other momentum invariants follow similarly.

$$\mathcal{M} = \iint h(u - fy) \, dx \, dy \quad [29]$$

The Casimirs are given by eqn [30] for arbitrary functions $C(\cdot)$.

$$\mathcal{C} = \iint hC(q) \, dx \, dy \quad [30]$$

Thus, potential vorticity still plays a crucial role in the Hamiltonian description of the dynamics. Special cases of Casimirs are total mass ($C = 1$) and total circulation ($C = q$).

Stratification is easily incorporated. The hydrostatic primitive equations can be cast in Hamiltonian form isomorphic to that of eqn [28] when expressed in isentropic coordinates. Even the fully compressible stratified Euler equations, which form the most general system imaginable for (dry) dynamical meteorology, can be cast in an analogous form, although there are now additional dynamical variables associated with compressibility. The Casimirs are in this case given by eqn [31], where $\rho(x, y, z, t)$ is the density, $\theta(x, y, z, t)$ is the potential temperature, and $q = [(f\hat{\mathbf{z}} + \nabla \times \mathbf{v}) \cdot \nabla \theta]/\rho$ is the Ertel potential vorticity, with $\mathbf{v}$ and ∇ now acting in all three space dimensions.

$$\mathcal{C} = \iiint \rho C(q, \theta) \, dx \, dy \, dz \quad [31]$$

The invariance of the Casimirs is of course evident directly from the dynamical equations (eqn [32]) and reflects the material invariance of q and θ .

$$\begin{aligned} \frac{\partial q}{\partial t} + \mathbf{v} \cdot \nabla q &= 0, & \frac{\partial \theta}{\partial t} + \mathbf{v} \cdot \nabla \theta &= 0, \\ \frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) &= 0 \end{aligned} \quad [32]$$

The fully compressible stratified Euler equations are, in fact, a straightforward expression of Newton's second law, without constraints such as hydrostatic balance, provided they are expressed in Lagrangian coordinates (see **Dynamical Meteorology: Lagrangian Dynamics**). In Lagrangian coordinates, the dynamical variables are the positions and momenta of fluid elements, which are natural canonical variables. The thermodynamic fields can be expressed in terms of these variables: ρ can be written in terms of the Jacobian of particle positions (which describes the compression of the fluid), while θ can just be chosen as one of the Lagrangian coordinates. In this way, the fully compressible stratified Euler equations represent a canonical Hamiltonian system. But there are six

dynamical variables in the Lagrangian description, compared with only five in the Eulerian description; in transforming to Eulerian coordinates, a reduction of the phase space takes place. This is where the potential vorticity comes in. In Lagrangian coordinates, the potential vorticity is still materially conserved; but what symmetry does it correspond to? The answer is a particle-relabeling symmetry: if one rearranges fluid elements while preserving the same Eulerian fields, then the dynamics is unchanged. There is just enough freedom to do this, because there is one more Lagrangian than Eulerian variable. Upon reduction to the Eulerian description, this additional degree of freedom disappears, and the particle-relabeling symmetry becomes invisible. That is why potential vorticity conservation then appears in the form of a Casimir invariant.

Disturbance Invariants

Probably the most powerful application of Hamiltonian dynamics to dynamical meteorology arises in the context of studying the properties of disturbances to basic states. In fluid dynamics, the question of how to define the energy of a wave has often been a point of confusion if not contention. For example, in the case of a basic flow, if the wave energy is defined as the energy in the frame of reference moving with the basic flow, then it is positive definite but not conserved. On the other hand, if it is defined as the difference energy relative to the basic-flow energy, then it is conserved but not positive definite. One would like both properties in order to define normal modes, spectra, etc. Another problem, at first sight unrelated, arises with momentum. The momentum of a wave would appear to be zero (the average of a sinusoid is zero), yet waves can certainly transfer momentum; this is what drives the quasi-biennial oscillation in the tropical stratosphere, for example (see **Middle Atmosphere: Quasi-Biennial Oscillation**). How is one to describe this wave momentum?

In canonical Hamiltonian mechanics, the disturbance energy about an equilibrium is always quadratic; from this one assesses stability and defines normal modes. There is no ambiguity. So why are things not equally clear for fluid dynamics? The answer lies in the noncanonical Hamiltonian structure of virtually every fluid dynamical system in the Eulerian representation. If $\mathbf{u} = \mathbf{U}$ is a steady solution of a Hamiltonian system, then eqn [33] holds.

$$J \frac{\delta \mathcal{H}}{\delta \mathbf{u}} \bigg|_{\mathbf{u} = \mathbf{U}} = 0 \quad [33]$$

For a canonical system, the invertibility of J then implies that $\delta \mathcal{H}/\delta \mathbf{u} = 0$ at $\mathbf{u} = \mathbf{U}$. This means that $\mathbf{U}$ is a conditional extremum of $\mathcal{H}$, and $\mathcal{H}[\mathbf{u}] - \mathcal{H}[\mathbf{U}]$ is quadratic in the disturbance. However, for a noncanonical system none of this follows and the disturbance energy is generally linear in the disturbance.

Pseudoenergy

Hamiltonian structure provides the solution to this quandary. Equation [33] is locally the same as the equation defining the Casimirs, which means that $\delta \mathcal{H}/\delta \mathbf{u}$ is locally parallel to $\delta \mathcal{C}/\delta \mathbf{u}$

for some $\mathcal{C}$ (a different $\mathcal{C}$ for each choice of $\mathbf{U}$). In other words, there exists a Casimir $\mathcal{C}$ such that eqn [34] holds.

$$\left. \frac{\delta \mathcal{H}}{\delta \mathbf{u}} \right|_{\mathbf{u}=\mathbf{U}} = \left. \frac{\delta \mathcal{C}}{\delta \mathbf{u}} \right|_{\mathbf{u}=\mathbf{U}} \quad [34]$$

Now, both $\mathcal{H}$ and $\mathcal{C}$ are invariants, and the combined invariant $\mathcal{H} + \mathcal{C}$ satisfies the extremal condition $\delta(\mathcal{H} + \mathcal{C}) = 0$ at $\mathbf{u} = \mathbf{U}$. We have thus constructed what we wanted, namely a disturbance quantity that is conserved and is locally quadratic in the disturbance (eqn [35]).

$$\mathcal{A} = (\mathcal{H} + \mathcal{C})[\mathbf{u}] - (\mathcal{H} + \mathcal{C})[\mathbf{U}] \quad [35]$$

This quantity is known as the pseudoenergy. Provided one has a complete set of Casimirs, eqn [34] can always be solved for a Hamiltonian system and the pseudoenergy can always be constructed according to eqn [35]. This is one of the great attractions of Hamiltonian dynamics: it provides systematic recipes in abstract terms, which can be worked out for any particular application.

A particularly illuminating application is the subject of available potential energy, highly useful in energy budget analyses. We demonstrate the method in the case of the three-dimensional stratified Boussinesq equations. The energy is given by eqn [36].

$$\mathcal{H} = \iint \left\{ \frac{1}{2} \rho_s |\mathbf{v}|^2 + \rho g z \right\} dx dy dz \quad [36]$$

Here ρ_s is the constant reference-state density, and the dynamical variables are $\mathbf{v}$ and ρ , for which eqns [37] hold.

$$\frac{\delta \mathcal{H}}{\delta \mathbf{v}} = \rho_s \mathbf{v}, \quad \frac{\delta \mathcal{H}}{\delta \rho} = g z \quad [37]$$

The term $\rho g z$ in eqn [36] is the gravitational potential energy, and is linear in the dynamical variables. Now consider disturbances to a stably stratified, resting basic state $\mathbf{v} = 0$, $\rho = \rho_0(z)$. Although the Casimirs of this system include functions of the potential vorticity, because the basic state is at rest, $\delta \mathcal{H} / \delta \mathbf{v} = 0$ at $\mathbf{v} = 0$ and this dependence is unnecessary, so we may consider Casimirs of the form of eqn [38].

$$\mathcal{C} = \iiint C(\rho) dx dy dz \quad \text{with} \quad \frac{\delta \mathcal{C}}{\delta \rho} = C'(\rho) \quad [38]$$

Equation [34] then leads to the condition $C'(\rho_0) = -gz$. This is the defining relation for the function $C(\cdot)$. Thus, one has to express gz in terms of the same argument ρ_0 . This can be done by inverting the functional dependence $\rho_0(z)$ to obtain $Z(\rho_0)$, where $Z(\rho_0(z)) = z$. This is always possible provided $\rho_0(z)$ is monotonic, which is the case for a stably stratified basic state. One then has eqn [39].

$$C(\rho) = - \int_{\rho_0}^{\rho} g Z(\tilde{\rho}) d\tilde{\rho} \quad [39]$$

From this the pseudoenergy of eqn [35] takes the form [40].

$$\mathcal{A} = \iiint \left\{ \frac{\rho_s}{2} |\mathbf{v}|^2 + (\rho - \rho_0) g z - \int_{\rho_0}^{\rho} g Z(\tilde{\rho}) d\tilde{\rho} \right\} dx dy dz \quad [40]$$

The first term in the spatial integrand is the kinetic energy and is positive definite; the last two terms can be rewritten as in eqn [41].

$$- \int_0^{\rho - \rho_0} g [Z(\rho_0 + \tilde{\rho}) - Z(\rho_0)] d\tilde{\rho} \quad [41]$$

This is self-evidently positive definite for $d\rho_0/dz < 0$ and has the small-amplitude quadratic approximation [42].

$$- \frac{g(\rho - \rho_0)^2}{2(d\rho_0/dz)} \quad [42]$$

Equation [41] is the exact, finite-amplitude expression for the available potential energy (see **General Circulation of the Atmosphere: Energy Cycle**) of disturbances to a stably stratified, resting basic state $\rho_0(z)$, while eqn [42] is its more familiar small-amplitude counterpart, widely used in the theory of internal gravity waves (see **Gravity Waves: Buoyancy and Buoyancy Waves: Theory**). Similar constructions can be performed to define the available potential energy of any stratified fluid system.

Although the small-amplitude expression of eqn [42] appears to be singular in regions where $d\rho_0/dz = 0$, the finite-amplitude expression of eqn [41] remains perfectly well-defined in such regions.

Pseudomomentum

The same kind of reasoning can be applied for disturbances to zonally symmetric (x -invariant) basic states, assuming that the underlying system possesses the same symmetry. For such states, with $\partial \mathbf{U} / \partial x = 0$, Noether's theorem implies that the zonal impulse or momentum invariant satisfies eqn [43].

$$\left. J \frac{\delta \mathcal{M}}{\delta \mathbf{u}} \right|_{\mathbf{u}=\mathbf{U}} = 0 \quad [43]$$

But just as with eqn [33], there is a Casimir $\mathcal{C}$ such that $\delta(\mathcal{M} + \mathcal{C}) = 0$ at $\mathbf{u} = \mathbf{U}$; with this $\mathcal{C}$, one may immediately construct the invariant [44], which is quadratic to leading order in the disturbance.

$$\mathcal{A} = (\mathcal{M} + \mathcal{C})[\mathbf{u}] - (\mathcal{M} + \mathcal{C})[\mathbf{U}] \quad [44]$$

This quantity is known as the pseudomomentum.

We calculate the pseudomomentum for the case of barotropic flow on the beta-plane. Suppose we are given a monotonic basic state $q_0(y)$. From eqns [14] and [16], with q in place of ω , we have eqn [45].

$$\frac{\delta \mathcal{M}}{\delta q} = y, \quad \frac{\delta \mathcal{C}}{\delta q} = C'(q) \quad [45]$$

The extremal condition $\delta(\mathcal{M} + \mathcal{C}) = 0$ at $q = q_0$ then leads to $C'(q_0) = -y$. This is now isomorphic to the construction of the available potential energy, replacing gz with y and ρ with q . If we define the function $Y(\cdot)$ by $Y(q_0(y)) = y$, then evidently eqn [46] holds.

$$\mathcal{A} = \iint \left\{ - \int_0^{q - q_0} [Y(q_0 + \tilde{q}) - Y(q_0)] d\tilde{q} \right\} dx dy \quad [46]$$

The small-amplitude approximation to the spatial integrand is given by eqn [47].

$$\frac{(q - q_0)^2}{2(dq_0/dy)} \quad [47]$$

Equations [46] and [47] are evidently negative definite for $dq_0/dy > 0$, which is the case when q_0 is dominated by βy . These rather peculiar expressions have no obvious relation to zonal momentum at first sight, but they nevertheless explain why it is that Rossby waves always exert an eastward (positive) force when they leave a source region, and a westward (negative) force when they dissipate and deposit their momentum in a sink region: they carry negative pseudomomentum.

The general nature of the derivation ensures that exactly the same expressions hold for any balanced model having the basic form of eqn [13]. If the basic state q_0 is chosen to be the zonal mean $\bar{q}$, then the zonal mean of eqn [47] becomes eqn [48], where $q' = q - \bar{q}$

$$-\frac{\overline{q'^2}}{2\bar{q}_y} \quad [48]$$

In the case of stratified QG dynamics, the negative of eqn [48] is known as the Eliassen–Palm wave activity (*see Middle Atmosphere: Zonal Mean Climatology*), which has been widely used in dynamical meteorology to assess the effect of Rossby waves on the zonal mean flow. It is such an effective diagnostic precisely because it represents negative pseudomomentum. Moreover, and importantly, its use is not restricted to waves. The exact, finite-amplitude expression of eqn [46] ensures that the concept of pseudomomentum applies to fully nonlinear, even turbulent disturbances.

The robust negative definiteness of the pseudomomentum of balanced disturbances explains a great deal about the general circulation of the atmosphere. Propagation of synoptic-scale Rossby waves away from their source region in the baroclinic storm tracks implies an eastward force in the storm track regions, accounting for the maintenance of the westerlies (*see General Circulation of the Atmosphere: Mean Characteristics*). The westward momentum deposition associated with breaking planetary-scale Rossby waves in the stratosphere drives the poleward Brewer–Dobson circulation (*see Middle Atmosphere: Zonal Mean Climatology*), which is responsible for the observed distribution of ozone and other chemical species in the stratosphere.

Stability Theorems

The pseudoenergy and pseudomomentum are, by their construction, conserved quantities that are quadratic to leading order in the disturbance quantities. In fact, their quadratic approximations are exactly conserved by the linearized dynamics. (The quadratic approximation to the pseudoenergy is the Hamiltonian of the linearized dynamics.) When either of these quantities is sign-definite for a given basic state, it follows that that basic state is stable to normal-mode instabilities. Indeed, in order to reconcile exponentially growing disturbances with conservation of pseudoenergy and

pseudomomentum, the latter quantities must vanish for such disturbances. This fact provides a useful constraint on the structure of normal-mode instabilities, as well as a powerful unifying framework between different models.

This simple framework accounts for virtually every known stability theorem in dynamical meteorology. For resting, stratified basic states in unbalanced models, with pseudoenergy like eqn [40] for the Boussinesq model, the condition of positive definite pseudoenergy is the statement of static stability (*see Dynamical Meteorology: Static Stability*). For basic flows in axisymmetric or symmetric stratified unbalanced models, the same condition is the statement of symmetric stability (*see Dynamical Meteorology: Symmetric Stability*), which reduces to Rayleigh’s centrifugal stability theorem in the special case of axisymmetric homogeneous flow (*see Dynamical Meteorology: Inertial Instability*). These stability theorems are all quite analogous to static stability. A different situation arises for balanced models. There, the pseudoenergy can take either sign depending on the basic flow. The positive-definite and negative-definite cases correspond respectively to Arnold’s first and second stability theorems. (They are analogous to the stability of a rigid body rotating about an axis of symmetry corresponding respectively to a maximum or minimum moment of inertia.) In the special case of a parallel basic flow, Arnold’s first theorem states that the flow is stable if $u_0/(dq_0/dy) < 0$, which is the Fjørtoft–Pedlosky theorem.

With regard to pseudomomentum for balanced models, eqn [46] is sign-definite whenever dq_0/dy is sign-definite. For barotropic flow with $q = \omega$, this corresponds to Rayleigh’s inflection-point theorem; on the beta-plane with $q = \omega + \beta y$, to the Rayleigh–Kuo theorem; and for stratified QG flow with q given either by its multilevel forms q_i or by eqn [21] in the continuously stratified case, to the Charney–Stern theorem. For stratified QG dynamics in the presence of a lower boundary, the second terms of eqns [23] and [24] become relevant and there is an additional contribution to the pseudomomentum involving the temperature distribution on the lower boundary; it is isomorphic to the interior eqns [46], [47] and [48], replacing q with ψ_z . Since the climatological temperature gradient along the Earth’s surface is towards the Equator, the pseudomomentum associated with surface disturbances is generally positive. In this case the Charney–Stern stability criterion is not satisfied for observed flows; on the other hand, normal-mode instabilities are generally required to involve both temperature disturbances on the lower boundary and potential-vorticity disturbances in the interior, in order to create a disturbance with zero total pseudomomentum. The Charney model of baroclinic instability (*see Dynamical Meteorology: Baroclinic Instability*) is the best-known example of this. In the presence of an upper boundary, there is a further contribution to the pseudomomentum, with opposite sign to the lower contribution in accord with eqn [24]. Thus in the Eady model of baroclinic instability, where the potential vorticity is uniform and the interior contribution to the pseudomomentum disappears, the instability can arise from the interaction of disturbances on the upper and lower boundaries that together add up to zero total pseudomomentum.

These statements all concern normal-mode stability. But what can be said about stability goes much further than this.

The existence of finite-amplitude disturbance invariants suggests the possibility of nonlinear, or Liapunov stability: namely, that small disturbances stay small for all time, where small is defined in terms of some disturbance norm. Mathematically, we say that a basic state $\mathbf{U}$ is Liapunov stable to disturbances $\mathbf{u}'$ in a given norm $\|\mathbf{u}'\|$ if for all $\varepsilon > 0$ there exists a $\delta(\varepsilon) > 0$ such that eqns [49] hold.

$$\|\mathbf{u}'(0)\| < \delta \Rightarrow \|\mathbf{u}'(t)\| < \varepsilon \quad \text{for all } t \quad [49]$$

Let us see how this applies to static stability for the Boussinesq model considered earlier. Suppose that the basic state has $d\rho_0/dz < 0$ and that furthermore the basic-state density gradients are bounded according to [50] for some constants c_1, c_2 .

$$0 < c_1 \leq -g \frac{dz}{d\rho_0} = -\frac{g}{d\rho_0/dz} \leq c_2 < \infty \quad [50]$$

Then eqn [41] for the available potential energy is bounded from above and below according to eqn [51].

$$\frac{1}{2} c_1 (\rho - \rho_0)^2 \leq [41] \leq \frac{1}{2} c_2 (\rho - \rho_0)^2 \quad [51]$$

Define the disturbance norm by eqn [52], with $c_1 \leq \lambda \leq c_2$.

$$\begin{aligned} \|(\mathbf{v}, \rho - \rho_0)\|^2 &= \iiint \frac{1}{2} \{ \rho_s |\mathbf{v}|^2 + \lambda (\rho - \rho_0)^2 \} \, dx \, dy \, dz \end{aligned} \quad [52]$$

Then using eqn [51] we obtain the chain [53] of inequalities, valid for any time t , involving the pseudoenergy $\mathcal{A}$ of eqn [40].

$$\begin{aligned} \|(\mathbf{v}, \rho - \rho_0)(t)\|^2 &\leq \frac{\lambda}{c_1} \mathcal{A}(t) = \frac{\lambda}{c_1} \mathcal{A}(0) \\ &\leq \frac{c_2}{c_1} \|(\mathbf{v}, \rho - \rho_0)(0)\|^2 \end{aligned} \quad [53]$$

With the choice $\delta = \sqrt{c_1/c_2} \varepsilon$, eqn [53] establishes Liapunov stability in the norm defined by eqn [52]. Conservation of pseudoenergy is clearly central to the proof.

The finite-amplitude stability of stably stratified flow is not too surprising; it corresponds to physical intuition, and indeed motivates the very concept of available potential energy, which has a long pedigree. What is perhaps more surprising is that exactly the same kinds of constructions can be made for all of the stability theorems mentioned above, and for virtually any model within the same family. They can also be used to obtain rigorous upper bounds on the saturation of normal-mode instabilities, by considering the initial unstable flow (plus infinitesimal disturbance) to be a finite-amplitude disturbance to a stable basic state.

The study of hydraulic flow is one branch of a broader field of fluid mechanics dealing with the dynamics of density stratified flow under the influence of a gravity field. It has a natural application to the stratified atmosphere and ocean. The field of hydraulics is distinguishable from other studies of stratified flow by its emphasis on layered flow and the use of the hydrostatic or long-wave approximation. Typically, in hydraulic flow formulations, the fluid system is composed of one or more homogeneous fluid layers, separated by sharp interfaces with density discontinuities. This formulation, together with the hydrostatic assumption, insures that the velocity is nearly uniform with height within each layer. In this way, a continuous problem is reduced to a problem with one or more discrete layers; this results in a vast reduction in the number of degrees of freedom. The possibilities for mathematical analysis, numerical computation, and physical conceptualization are greatly enhanced by the simple formulation of hydraulic theory.

Historically, the field of hydraulics arose out of and is still largely involved in, the study of natural river flow and engineering problems related to water flow in channels. Its application to atmosphere and ocean dynamics is more recent. Beginning in the 1950s, a growing number of atmospheric applications have been suggested. On large scales, CG Rossby, G Benton, and NA Phillips developed two-layer mathematical models of the midlatitude atmosphere including the Coriolis force. On smaller scales, following the pioneering work of RR Long and M Tepper, a variety of atmospheric phenomena have been treated with hydraulic models. Cool outflowing air from thunderstorms, sea breeze fronts, and the leading edges of cold fronts all behave like gravity currents. Existing cool layers beneath marine inversions and frontal layers behave hydraulically in mountainous areas, causing barrier jets, gap jets, hydraulic jumps, severe downslope winds, and wake eddies. Cold high terrain can generate layered cold air avalanches and katabatic winds.

In oceanography too, hydraulic theory has found wide application. Basin-to-basin exchange of water masses is limited by hydraulic control at sills and straits. The propagation of tidal currents and tsunamis is controlled by the long-wave speed. Turbidity currents slump into the deep ocean according to gravity current dynamics. Coastally trapped currents obey a modified set of hydraulic equations. Even large-scale wind-driven ocean currents are often modeled as two layers, defined by the thermocline, with wind stress and the Coriolis force playing dominant roles.

The theory of hydraulic flow is based on a few fundamental definitions and concepts. These are reduced gravity, the long-wave speed, Froude number, hydraulic control, conjugate states, the hydraulic jump, and gravity or density current.

Reduced gravity (g') is a measure of the effective magnitude of gravity acting on layers of different density. It is defined as the product of the acceleration of gravity ($g = 9.81 \text{ m s}^{-2}$) times the relative density difference $\Delta\rho/\rho$ between the two superposed layers, thus $g' = (\Delta\rho/\rho)g$. In the compressible atmosphere, the relative density difference is approximately the difference in potential temperature (Θ), so that $g' = (\Delta\Theta/\Theta)g$. For example, if the air above an inversion is 3° warmer than the air below, and the average potential temperature is 300 K, the effective gravity is $g' = (3/300)g = 0.0981 \text{ m s}^{-2}$. The long-wave speed for a single layer is given by $C = (g'H)^{1/2}$, where H is the depth of the layer. If a cool marine layer of air has an effective gravity of $g' = 0.1$ and a depth of 1000 m, long gravity waves will propagate along it at a speed of $C = (0.1 \times 1000)^{1/2} = 10 \text{ m s}^{-1}$.

The Froude number plays a central role in hydraulic theory. It is defined as the ratio of flow speed (u) to long-wave speed (C), i.e., $(Fr) = u/C$. It is related to the ratio of kinetic energy to potential energy in a layer but is more useful as a measure of whether waves can move upstream against the current. Flows are categorized as subcritical, critical, or supercritical according to whether the Froude number is less than, equal to, or greater than unity. In supercritical flow ($(Fr) > 1$), long waves cannot move upstream or even stand steady against the fluid flow. As the long waves are usually the fastest waves in the system, information carried by waves cannot then be felt upstream of a disturbance. The nature of a fluid response to any disturbance is highly sensitive to the Froude number.

Hydraulic control occurs whenever a layered flow is forced to transition from subcritical to supercritical flow by the narrowing of a channel or valley, the rising of a sill or mountain, or the alteration of some other geometric or external parameters (e.g., Coriolis force, coastal slope, etc.). Downstream of the control point, i.e., the point where the Froude number is unity, supercritical flow prevents information from propagating upstream. As a result, the amount of flow through the channel cannot be altered from downstream. Only the upstream conditions and control point characteristics have an influence.

Conjugate states are defined as multiple states of flow, defined by fluid speed and layer depth, with identical mass and momentum flux. They can be computed easily in the hydraulic formalism. If a flow has a conjugate state, it can, in principle, jump spontaneously to its other state, without the loss or gain of mass or momentum. Most commonly, this occurs in a hydraulic jump (i.e., an abrupt thickening of a layer), where the energy may be dissipated by turbulence, but mass and momentum are conserved. Jumps are commonplace events in rivers, and related phenomena have been identified in the atmosphere and ocean.

A so-called gravity current or density current occurs when a new fluid pushes its way over or under an existing denser or less dense fluid, under the influence of gravity. While it resembles a hydraulic jump, a density current is not a sudden thickening of a preexisting layer, but the introduction of a new fluid layer.

The literature is not clear on whether all layered formulations of stratified fluid mechanics should be classified as 'hydraulics'. When friction or Coriolis forces dominate, the term hydraulics is less often used.

Introduction

Inertial instability is a fundamental, but infrequently documented, hydrodynamic instability characterized by strongly divergent anticyclonic flow. It is the geophysical analog to the centrifugal (or Taylor–Couette) instability in fluid dynamics examined by Rayleigh and Taylor nearly a century ago. Bergen School meteorologists seeking an explanation for cyclogenesis pioneered inertial instability research in the 1930s and 1940s. However, the triumph of baroclinic instability theory and balanced dynamics in the 1950s and 1960s sharply curtailed interest in inertial instability. A revival of research during the past two decades, particularly in middle-atmosphere and mesoscale dynamics, has led to a growing appreciation of the role of inertial instability in geophysical flows. Today, inertial instability arises in a wide range of subjects: the dynamics of mesoscale convection and monsoons, wave generation and breaking in the stratosphere and mesosphere, and the maintenance of jets in planetary atmospheres and equatorial oceanography. Below, we examine what inertial instability looks like physically, how it is represented mathematically, and how it is manifested geophysically. Those new to the subject may wish to begin with the latter.

Physical Description

Centrifugal instability occurs in the Taylor–Couette problem when the angular momentum of a fluid contained between two rotating cylinders (Figure 1(a)) decreases radially outward, violating Rayleigh’s stability criterion. Parcels then rearrange themselves to achieve a stable radial profile of angular momentum.

Inertial instability is the geophysical equivalent of centrifugal instability and occurs when angular momentum decreases as one moves outward from the axis of rotation of the flow. This can be visualized on the global scale (Figure 1(b)) by imagining the roles of the cylinders being played by latitude lines, with the Equator serving as the inner cylinder. The latitude at which angular momentum is nondecreasing outward from the rotation axis forms the outer cylinder.

This analogy between centrifugal and inertial instabilities is correct only if the rotation in the Taylor–Couette apparatus is equated to the total vertical rotation of the flow in the geophysical case. In meteorological terminology, the rotation in Figure 1(b) is the sum of the planetary and relative vertical vorticities. From this viewpoint, inertial instability should be expected where the relative vorticity is opposite in sign to the planetary vorticity, and at least equal in magnitude to it. The threshold for inertial instability – the latitude corresponding to the outer cylinder in Figure 1(b) – is thus the location of zero absolute vorticity. With some restrictions, this is proved mathematically in the next section.

Figure 1 (a) Centrifugal instability in the Taylor–Couette experiment and (b) inertial instability near the equator. Adapted with permission from Hua, B.L., Moore, D.W., Le Gentil, S., 1997. Inertial nonlinear equilibration of equatorial flows. *Journal of Fluid Mechanics* 331: 345–371.

Inertial instability, like centrifugal instability, leads to roll-like vortical motions. The flattened, 'pancake'-like divergent circulations of inertial instability ([Figure 2](#)) attempt to reduce the anticyclonic local rotation via momentum transports so that the total rotation is the same sign throughout the domain.

An inertially unstable flow can exist on a variety of scales. As illustrated in [Figures 1 and 2](#), the flow can be as large as a zonally symmetric latitudinal ring of air around the Earth. It can also occur on scales as small as a mesoscale vortex. When viewed from the perspective of a circular vortex, this instability is triggered when a very strong outward pressure gradient force and the centrifugal force combine to overwhelm the Coriolis force and lead to the breakdown of balance.

In layman's terms, the salient point of inertial instability research is that a planet's rotation sets a local rotational

'speed limit' beyond which violations are corrected via inertial instability. This 'speed limit' can be indirectly inferred from weather charts in a number of ways: for example, the strong tendency for nonnegative absolute vorticity in the Northern Hemisphere, and also the complete absence of intense 'bull's-eye' high-pressure centers analogous to 'bomb' cyclones.

Inertial instability depends on planetary rotation and the horizontal shear and/or curvature of the horizontal wind. In this sense, it shares an affinity with barotropic instability. However, the rapid, strongly divergent motions associated with inertial instability invite analogies with another fundamental, strongly ageostrophic instability: static instability. This analogy is strengthened by the close similarity in the derivation of these two instabilities' criteria, discussed below.

Figure 2 Schematic view of inertially unstable circulations in (y, z) . DIV and CONV refer to regions of divergence and convergence due to the horizontally divergent inertial circulations, shown in heavy bold arrows. Conservation of mass leads to the vertical motions shown in the lighter arrows, which adiabatically create the warm and cold temperature anomalies labeled W and C respectively. Adapted with permission from Dunkerton, T.J., 1981. On the inertial stability of the equatorial middle atmosphere. *J. Atmos. Sci.* 38: 2354–2364, and Hayashi, H., Shiotani, M., Gille, J.C., 1998. Vertically stacked temperature disturbances near the equatorial stratopause as seen in cryogenic limb array etalon spectrometer data. *Journal of Geophysical Research* 103: 19469–19483.

Figure 3 Schematic illustrating the physical situation posed in the mathematical derivation of the inertial instability criterion (eqn [8]), in which a parcel (small circle) in a background flow with horizontal shear is subject to a perturbation (heavy arrow).

Mathematical Criteria for Instability

Inertial instability represents a large departure from geostrophic balance. As a result, inertial instability theory cannot rely on quasi-geostrophic or nonlinear balances to facilitate a generalized theory, making it a far less tractable problem than barotropic or baroclinic instability. In fact, no fully three-dimensional theory for inertial instability exists currently. Instead, the classic derivation relies on the parcel-mode approach, an extremely simplified flow geometry, and ignores nonlinear, frictional, and diabatic effects. Even so, the result is remarkably useful when applied to observed and simulated flows.

We begin by assuming that we have a perturbed parcel embedded in a purely zonal geostrophic flow, as illustrated in **Figure 3**. The horizontal equations of motion describing the parcel are:

$$\frac{D_H u}{Dt} = f v_{ag} \quad [1]$$

$$\frac{D_H v_{ag}}{Dt} = f(u_g - u) \quad [2]$$

In these equations, the horizontal Lagrangian derivative $D_H/Dt = \partial/\partial t + u\partial/\partial x + v\partial/\partial y$ and f is the Coriolis parameter (assumed to be constant for simplicity). In eqn [2], the meridional pressure gradient term has been rewritten in terms of the geostrophic wind.

These two equations can be combined into one equation for the meridional ageostrophic wind in the following manner. Taking the Lagrangian derivative of eqn [2] yields

$$\frac{D_H^2 v_{ag}}{Dt^2} = f \left(\frac{D_H u_g}{Dt} - \frac{D_H u}{Dt} \right) \quad [3]$$

The second term in the parenthesis in eqn [3] can be replaced with the right-hand side of eqn [1], coupling the two equations of motion. The first term in the parenthesis can also be related to the meridional ageostrophic wind via the following approximation:

$$\frac{D_H u_g}{Dt} \approx v \frac{\partial u_g}{\partial y} = -v_{ag} \zeta_g \quad [4]$$

The relation in eqn [4] derives from the steady, zonally uniform mass field in **Figure 3**. It also assumes that the parcel

will not locally change the geostrophic wind but it can advect geostrophic relative vorticity meridionally; thus the analysis is non-quasi-geostrophic but omits the two-way interaction of the geostrophic adjustment problem.

Insertion of eqns [1] and [4] into eqn [3] and rearrangement leads directly to

$$\frac{D_H^2 v_{ag}}{Dt^2} + [f(f + \zeta_g)] v_{ag} = 0 \quad [5]$$

This second-order differential equation bears a close resemblance to the stability equation for static instability, with the meridional ageostrophic wind replacing the vertical displacement and $f(f + \zeta_g)$ replacing the buoyancy frequency. As in the static stability problem, we assume a wave solution and obtain the following cases:

$$f(f + \zeta_g) > 0$$

stable inertial oscillation with period

$$\frac{2\pi}{[f(f + \zeta_g)]^{1/2}} \quad [6]$$

$$f(f + \zeta_g) = 0 \quad \text{inertial neutrality} \quad [7]$$

$$f(f + \zeta_g) < 0$$

$$\text{inertial instability with e-folding time } \frac{1}{[-f(f + \zeta_g)]^{1/2}} \quad [8]$$

Note that the inertial oscillation period in eqn [6] reduces to the usual textbook form if $\zeta_g = 0$ the more general form in eqn [6] has been applied successfully to constant-pressure radiosonde trajectory periodicities. Weak inertial stability is analogous to weak static stability, in which forcing leads to a larger response than in strongly stable conditions.

The criterion in eqn [8] can be interpreted in a variety of ways. In the Northern Hemisphere, it is equivalent to negative geostrophic absolute vorticity. For statically stable conditions, eqn [8] implies negative *potential* vorticity in a geostrophic flow in the Northern Hemisphere. If eqn [8] is calculated on an isentropic surface then it is identical to the criterion for symmetric instability (see **Dynamical Meteorology: Symmetric Stability**). Interestingly, the necessary criterion for barotropic instability is the meridional derivative of eqn [8].

The e-folding times of inertial instability are, by eqn [8], dependent on the latitude and the magnitude of the anomalous absolute vorticity. Observations and modeling studies suggest e-folding times as short as a few hours in the mesoscale midlatitude troposphere and around one day in the equatorial middle atmosphere. These time scales are much longer than for static instability but are usually shorter than for barotropic instability.

Extensions beyond eqn [8] are possible in some cases. For a circular vortex, the criterion in eqn [8] is modified only slightly, with the sum of the shear and curvature vorticities replacing the geostrophic relative vorticity. Extension of the

analysis to the beta plane does not alter the instability criterion, although the condition for stability becomes necessary, no longer sufficient. On the sphere, the metric terms due to the Earth's curvature can alter the criterion, but the change is significant only for high wind speeds and/or high latitudes. The vertical equation of motion may be incorporated into the analysis via the thermal wind law; the resulting instability criterion is eqn [8], with the absolute vorticity replaced with the Ertel potential vorticity. Friction in the form of Rayleigh drag stabilizes the flow linearly, i.e., the more drag there is, the less unstable/more stable the flow is. Extension of the theory to zonally asymmetric flows has been achieved but does not yield an alternative criterion; in general eqn [8] is used locally with good results, except in very strong anticyclones.

Unfortunately, the assumptions in the analysis above preclude any insight into the vertical scale of the instability. The growth rates for inertial instability are greatest at smallest scales; it is hypothesized that eddy diffusion damps these scales out and leads to a preferred intermediate vertical scale. However, the instability itself may be the source of the turbulent eddies that in turn select the vertical scale of the instability. Thus the eddy diffusion hypothesis for vertical scale selection, which depends on externally prescribed approximations such as Rayleigh drag, is incomplete.

Observed Phenomena Related to Inertial Instability

Inertial instability is possible wherever the anticyclonic relative vorticity rivals the Coriolis parameter in magnitude. Therefore, it is not confined to any one region of the planet, although it is

likeliest where the Coriolis parameter is smallest, i.e., the tropics.

Middle Atmosphere

Large-scale inertial instability is observed in the equatorial lower mesosphere, often lasting about a week and occurring within a week or two of the boreal winter solstice. The instability develops in regions of negative absolute vorticity (Figure 4) on the poleward flank of the stratopause semiannual oscillation easterlies; there is also evidence for it around the summer solstice. Its hallmarks are layered, nearly stationary 'pancake structures' in the eddy temperature field (Figure 5) that have a latitudinal width of 10–20 degrees of latitude and a vertical wavelength of roughly 10 km.

Numerical simulations and observations have shown that Rossby wave breaking in the tropics acts as a trigger for the onset of equatorial inertial instability and influences its zonally asymmetric nature in winter. The divergent character of the instability, and some recent observational work, suggest a role for inertial instability in the latitudinal transport of tracers in the tropical middle atmosphere.

Recent research strongly indicates that Rossby wave-triggered inertial instability excites the two-day wave of the equatorial stratopause region. The instability may also play a role in some stratospheric sudden warmings and other high-latitude phenomena.

Upper Troposphere

Inertial instability has been sought for in jet stream analyses since the 1940s. A long-term climatology of inertial instability

Figure 5 Vertically layered ‘pancake structures’ in the lower mesosphere in LIMS eddy temperatures (contour interval 1 K, negative regions shaded) at the international dateline on 10 December 1978, at the beginning of a week-long episode of inertial instability. Note that the temperature anomalies are strongest just south of 10° N, where the inertial instability is centered in [Figure 4](#), and that anomalies of the opposite sign exist near 30° N, as predicted by the schematic in [Figure 2](#).

based on NCEP geopotential heights ([Figure 6](#)) reveals why this has been a difficult search: the criterion for the instability is achieved in the data-rich midlatitudes only once every few years at most. (The occurrence rate is of course higher for higher-resolution data sets, but is still rare.) However, [Figure 6](#) suggests that inertial instability is a fairly common phenomenon in the subtropical upper troposphere, particularly on the equatorward flank of the East Asian jet. Recent work has shown layered disturbances in low-PV regions near the tropopause just south of Japan.

Inertial instability can enhance the outflow from mesoscale convective systems such as thunderstorms, ‘tropical plumes’, and hurricanes (the Rossby radius of deformation, an estimator of the outflow width, is closely related to eqn [8] and is infinite in the case of inertial instability). However, the evidence for its role in both hurricane outflow and severe thunderstorms is mixed. In [Figure 7](#), the upper-tropospheric flow pattern for the devastating 3 May 1999 Oklahoma City, Oklahoma, tornado outbreak is depicted. Inertially unstable regions are colocated with strong divergence aloft and severe weather at the surface in this case, but not in others. The relationship between inertial instability and convection is still not well understood.

Inertial instability may also have a connection to hazardous weather from an aviation perspective. The gravity wave

radiation expected from strongly anticyclonic regions, such as inertially unstable circulations, may lead to some otherwise unexplained instances of clear-air turbulence.

Lower-to-Middle Troposphere

Inertial instability below the jet stream level is confined to the tropics and a few rare instances in the midlatitudes. The cross-equatorial Asian monsoon circulation appears to accelerate toward the coast of India under the influence of inertial instability. The divergence – convergence couplets of inertial instability appear to determine the location of near-equatorial convection and the mean latitude of the Intertropical Convergence Zone.

Intense extratropical anticyclones may possibly exhibit inertial instability. This is the best explanation for an unforecast pre-dawn elevated convection event near the center of the mid-July 1995 Chicago heat wave high-pressure system. Elongated bands of light precipitation ([Figure 8](#)) coincided closely in time and space with a narrow region of negative potential vorticity ([Figure 9](#)). Very high-resolution model simulations of this event, shown in [Figure 10](#), indicate a checkerboard pattern of vertical motion (and thus divergence and convergence) strongly suggestive of [Figure 2](#). It appears that the

Figure 6 Climatology of inertial instability using National Centers for Environmental Prediction daily geopotential height analyses (horizontal resolution = 381km at 60° N) at 250 mb for December 1966–December 1994 (29 Decembers). Contours indicate the number of analyses in which eqn [8] was satisfied over the 899 days in the study. Figure courtesy Russ Schumacher, Colorado State University, and David Schultz, National Severe Storms Laboratory.

Figure 7 Eta model initial analysis of absolute geostrophic vorticity (shaded, only negative regions shown; scale is $\times 10^5 \text{ s}^{-1}$), geopotential height (heavy contours; in decameters), and horizontal divergence (light contours; scale is $\times 10^5 \text{ s}^{-1}$) at 300 mb over Texas and Oklahoma valid at 0000 UTC on 4 May 1999. The centroid of tornado reports at this time is indicated with a large T. Shaded regions, corresponding to inertial instability via eqn [8], are collocated with severe weather and with high values of divergence. The inertially unstable region over Texas was associated with 29 severe weather reports. Figure courtesy David Schultz, National Severe Storms Laboratory.

rising motions induced by the instability were substantial enough to cause condensation and elevated convection where strong subsidence would normally be expected.

Other Geophysical Fluids

Like the atmosphere, the oceans may also contain inertially unstable flows wherever the anticyclonic current is fast and the effect of the planetary rotation is weak. The layered structure of subthermocline equatorial ocean currents, reminiscent of the middle atmosphere 'pancake structures' and confined to within a degree or two of the Equator, has been linked with inertial instability. Furthermore, anticyclonic ocean eddies, even at high latitudes, can satisfy the criterion in eqn [8]. For example, the overwhelming tendency for 'spiral eddies' on the scales of a few kilometers to rotate cyclonically has been attributed to the limiting effects of inertial instability on small-scale anticyclones.

Farther afield, the atmospheres of Mars and the large gaseous planets are likely venues for inertial instability owing to their strong jet structures at low latitudes. Modeling studies suggest that the very strong shears on the equatorial flanks of the Martian jets should be inertially unstable, even in long-term means.

Figure 8 National Weather Service Doppler radar image from Sullivan, Wisconsin (circle at center of image) at 1133 UTC on 14 July 1995. The banded echoes extending east-southeast across central Wisconsin correspond to elevated convection at dawn during a deadly heat wave.

Figure 9 Potential vorticity (.025 PV unit contour interval, only negative values contoured) and equivalent potential temperature (2 K contour interval) at 4 km over the upper Midwest United States, as determined by a 24-hour forecast from the University of Wisconsin nonhydrostatic model (UW-NMS; horizontal resolution 6.67 km, vertical resolution 200–1000 m) valid at 1200 UTC 14 July 1995. Note the region of negative PV extending east-southeastward across central Wisconsin. The equivalent potential temperature field indicates the near-horizontal character of the flow over the region.

Figure 10 Cross-section of 24-hour forecast vertical motion (contoured every $0.025 \text{ m s}^{-1} = 2.5 \text{ cm s}^{-1}$) from UW-NMS valid 1200 UTC 14 July 1995. The cross-section slices NNW-SSE through the region of maximum inertial instability in Figure 9 (vertical mark below horizontal axis). The checkerboard pattern of vertical motion in the vicinity of the inertially unstable region should be compared with the schematic in Figure 2.

Summary

After several decades of off-and-on attention, inertial instability now seems firmly ensconced in the lexicon of geophysical fluid dynamics. The instability is at its largest and most observable in connection with breaking Rossby waves in the tropical middle atmosphere, but it can happen anywhere anticyclonic shear and/or curvature becomes unusually intense. Its purely horizontal origins and flattened pancake circulations make it orthogonal to static instability and much more difficult to observe. However, as a strongly ageostrophic instability it otherwise shares much in common with static instability. It is perhaps not too much of a stretch to call inertial instability by the nickname ‘horizontal convection’, while keeping in mind that rotation, not density, is at the heart of inertial instability.

Some outstanding research issues involving inertial instability include observation and theoretical explanation of its onset and three-dimensional structure; elucidation of its relationship to wave dynamics, other instabilities, and balanced dynamics; and further investigation of its role in mixing on a wide range of scales, from convection to planetary-scale flows.

Introduction

Kelvin–Helmholtz instability is the name given, since the 1940s, to an instability of a shear layer in a fluid, which is the mechanism of many phenomena observed in the atmosphere and oceans. It is said that in 1868 the German physiologist and physicist Hermann von Helmholtz first recognized the instability of a shear layer, by writing that “every perfect geometrically sharp edge by which a fluid flows must tear it asunder and establish a surface of separation, however slowly the fluid may move,” although this remark may seem to denote merely recognition of separation of a flow at an edge. However, in 1871 the British physicist William Thomson, Helmholtz’s friend who was later ennobled as Lord Kelvin, posed mathematically, and solved fully, a prototypical problem of linear instability of a horizontal vortex sheet between the uniform moving layers of two fluids of different densities, in an attempt to model the formation of ocean waves by the wind. Later, Helmholtz developed this model and applied it to the formation of billow clouds. At the same time the British physicist Lord Rayleigh was developing the theory of the instability of a shear layer, that is, a parallel flow in which the fluid speed varies across the layer.

These ideas were developed, extended, and applied in the twentieth century. An especially important extension is the instability of a horizontal shear layer in a stratified fluid, that is, a fluid whose density varies with height, because this models more realistically the mechanism of billow clouds, clear air turbulence, and other similar phenomena in the atmosphere.

The visionary British meteorologist Lewis Richardson recognized in the 1920s that atmospheric turbulence could be maintained only if the inertial instability due to shear could overcome the static stability due to heavier air being beneath lighter air. The essence of his argument can be recapitulated in terms of the energetics of the instability of a horizontal shear layer in a stratified fluid as follows. Suppose then that a basic flow of an incompressible inviscid fluid of variable density has velocity $U(z)\mathbf{i}$ and density $\rho(z)$, where $\mathbf{i}$ is a horizontal unit vector and z is the height. The essential mechanism of the instability is the conversion of the available kinetic energy of relative motion of the horizontal layers of the fluid into kinetic energy of a perturbation, overcoming the potential energy needed to raise or lower fluid when $d\rho/dz \leq 0$ everywhere, that is, when light fluid is always above heavier. Thus shear tends to destabilize and buoyancy to stabilize the flow. To quantify these tendencies, suppose that two neighboring fluid particles of equal volume, at heights z and $z + \delta z$, are

somehow interchanged. Then the increment of work δW per unit volume needed to overcome gravity and effect this interchange is

$$\delta W = -g\delta\rho\delta z$$

where g is the acceleration due to gravity and $\delta\rho = (d\rho/dz)\delta z$. In order that the horizontal momentum of the inviscid fluid is conserved in the interchange, the particle initially at height z will plausibly have final velocity intermediate between the velocities of the ambient fluid at its initial and final levels, say $(U + k\delta U)\mathbf{i}$, so that the other particle has final velocity $[U + (1 - k)\delta U]\mathbf{i}$ in order to conserve linear momentum, where $\delta U = (dU/dz)\delta z$ and k is some number between 0 and 1. Then the increment of kinetic energy δT per unit volume released by the interchange is

$$\begin{aligned}\delta T &= \frac{1}{2}\rho U^2 + \frac{1}{2}(\rho + \delta\rho)(U + \delta U)^2 - \frac{1}{2}\rho(U + k\delta U)^2 \\ &\quad - \frac{1}{2}(\rho + \delta\rho)[U + (1 - k)\delta U]^2 \\ &= k(1 - k)\rho(\delta U)^2 + kU\delta U\delta\rho\end{aligned}$$

on neglecting higher-order terms in $\delta\rho$ $(\delta U)^2$. For small increments,

$$\delta T = k(1 - k)\rho(\delta U)^2$$

on neglecting the inertial effects of the variation of density (this is a good approximation for instability in the atmosphere because the buoyancy effects of the variation of density there are almost always much greater). Thus,

$$\delta T = k(1 - k)\rho\left(\frac{dU}{dz}\right)^2(\delta z)^2 \leq \frac{1}{4}\rho\left(\frac{dU}{dz}\right)^2(\delta z)^2$$

with equality holding for $k = \frac{1}{2}$. Now a necessary condition for there being enough energy to effect this interchange, and hence for instability to occur, is that $\delta W \leq \delta T$, and therefore that

$$-g\frac{d\rho}{dz} \leq \frac{1}{4}\rho\left(\frac{dU}{dz}\right)^2$$

somewhere in the field of flow, or that

$$Ri(z) \leq \frac{1}{4}$$

where the local Richardson number is defined as the dimensionless quantity

$$Ri(z) \equiv -\frac{g d\rho/dz}{\rho(dU/dz)^2}$$

This criterion, namely that $Ri(z) \leq \frac{1}{4}$ somewhere in the flow, is a necessary condition for instability of the given basic flow, and

[†] Deceased.

so $Ri(z) > \frac{1}{4}$ everywhere in the flow is a sufficient condition for stability; it is called Richardson's criterion. The above argument for an incompressible inviscid fluid may be adapted for a perfect gas in adiabatic motion, and so for air in the atmosphere, by replacing the density with the potential density, and this leads again to Richardson's criterion but with the Richardson number redefined as

$$Ri(z) \equiv \frac{g}{T} \left(\frac{dT}{dz} + \Gamma \right) / \left(\frac{dU}{dz} \right)^2$$

where T is the absolute temperature and Γ the adiabatic lapse rate. For a perfect gas $\Gamma = g/c_p$, where c_p is the specific heat at constant pressure. In fact, $\Gamma \approx 8 \text{ K km}^{-1}$ in the troposphere.

Theory and Experiments

Now it is needful to go back to Kelvin's problem, and see a few of its details. Suppose that a basic horizontal flow of an incompressible inviscid fluid is given by

$$U(z) = \begin{cases} U_2, & \rho = \rho_2 \text{ for } z > 0 \\ U_1, & \rho = \rho_1 \text{ for } z < 0 \end{cases}$$

This gives a vortex sheet at $z = 0$, as sketched in [Figure 1](#). Kelvin was motivated by the special case with $\rho_2 \ll \rho_1$ to model wind

Figure 1 Sketch of (a) velocity and (b) density profiles in Kelvin's basic flow of two horizontal layers of fluid.

blowing on an ocean current. The occurrence of internal gravity waves in the special case with $U_2 = U_1$ may be anticipated. In any event, Kelvin took an irrotational flow coupled to a perturbation of the profile of the vortex sheet and resolved the perturbation into independent normal modes, with its flow quantities proportional to (or rather the real parts of functions proportional to)

$$\exp[i(kx + ly) + st]$$

where k and l are given horizontal wave numbers in the x - and y -directions (so the wavelengths in these directions are $2\pi/k$ and $2\pi/l$, respectively). He deduced, by solving an eigenvalue problem, that

$$s = -ik \frac{\rho_1 U_1 + \rho_2 U_2}{\rho_1 + \rho_2} \pm \left[\frac{k^2 \rho_1 \rho_2 (U_1 - U_2)^2}{(\rho_1 + \rho_2)^2} - \frac{g(k^2 + l^2)^{1/2} (\rho_1 - \rho_2)}{\rho_1 + \rho_2} \right]^{1/2}$$

Expressing $s = \sigma - i\omega$ in real and imaginary parts, ω as the frequency of the mode and σ as its relative growth rate are identified. It follows that if

$$k^2 \rho_1 \rho_2 (U_1 - U_2)^2 > g(k^2 + l^2)^{1/2} (\rho_1 - \rho_2) (\rho_1 + \rho_2)$$

then this mode may grow exponentially with

$$\sigma = \left[\frac{k^2 \rho_1 \rho_2 (U_1 - U_2)^2}{(\rho_1 + \rho_2)^2} - \frac{g(k^2 + l^2)^{1/2} (\rho_1 - \rho_2)}{\rho_1 + \rho_2} \right]^{1/2}$$

and the x -component of its phase velocity is the mass mean basic velocity

$$\frac{\omega}{k} = \frac{\rho_1 U_1 + \rho_2 U_2}{\rho_1 + \rho_2}$$

Now the flow is unstable if any one mode grows exponentially, and so if $\sigma > 0$ for any pair of real values k and l . But the formula above shows that $\sigma > 0$ for some modes with large values of k , provided that $U_2 \neq U_1$ and $\rho_1, \rho_2 > 0$, and therefore that all such two-layer flows are unstable to short waves. However, Kelvin himself showed that surface tension, as well as buoyancy, could in fact stabilize the flow. (In passing, one may note that the above formula for s gives the velocity of internal gravity waves at the interface of two fluids when $U_2 = U_1$.)

In 1931, Sydney Goldstein, Bernhard Haurwitz, and Geoffrey Taylor independently generalized Kelvin's model to deal with basic velocity and density profiles varying smoothly with height. Their results for various shear layers seemed to support Richardson's criterion, but John Miles and Louis Howard confirmed Richardson's criterion mathematically in the 1960s. Typical relative growth rates of a shear layer are found to be $\sigma \approx |U_2 - U_1|/10L$ when the Richardson number is appreciably less than a quarter (note that, by Richardson's criterion, $\sigma = 0$ if $Ri(z) \geq \frac{1}{4}$ everywhere), where L is the thickness of the layer. Taking $|U_2 - U_1| = 10 \text{ m s}^{-1}$ and $L = 100 \text{ m}$, as order of magnitude estimates for billow cloud formation, it is seen that the linear instability breaks up the shear layer with an e-folding time of about $\sigma^{-1} \approx 100 \text{ s}$. Thus Kelvin–Helmholtz instability is a transient process in the atmosphere. The transience presents

Figure 2 Kelvin's cat's eye pattern. This shows the streamlines near the level where the phase velocity of the waves equals the basic velocity of a smoothly varying profile of a homogeneous inviscid fluid.

one way to distinguish billow clouds from lee wave clouds, which are forced orographically.

In 1880 Kelvin himself examined the streamlines due to instability of a shear layer of an unstratified fluid, and found what is now called Kelvin's cat's eye pattern, shown in [Figure 2](#). Taylor showed in 1931 that for a stratified fluid the regions of closed streamlines alternate at slightly different levels.

As the sinusoidal waves of the linear instability grow, nonlinearity will moderate the growth. A vortex sheet and a shear layer will then begin to roll up, as shown in [Figure 3](#). Of course, instability in the atmosphere is not so neat as in the careful laboratory experiments of [Figure 3](#).

Atmospheric Phenomena

Kelvin–Helmholtz instability occurs in the atmosphere as a sporadic, but widespread, phenomenon. It is usually invisible and so can be dangerous as clear air turbulence. But it can be detected by radar or seen by chance as billow clouds when the humidity is such that the rising air in a vortex leads to condensation as cloud and the falling air leads to evaporation (see [Figure 4](#)). When seen at an angle, the lines of billow clouds are often called a ‘mackerel sky,’ this is because of their resemblance to the pattern on the back of a mackerel, the North Atlantic fish.

Kelvin–Helmholtz instability is not only of local significance. It, and the turbulence into which it usually develops, plays an important role in the energy budget of the atmosphere by transferring energy from the larger to smaller scales of motion until it is finally dissipated as heat by viscosity.

Further, it has been conjectured that shear instability in the absence of buoyancy plays a fundamental role in turbulence itself.

Introduction

The Kelvin wave is a large-scale wave motion of great practical importance in the Earth's atmosphere and ocean. Discovered by Sir William Thompson (who later became Lord Kelvin) in 1879, the Kelvin wave is a special type of gravity wave that is affected by the Earth's rotation and trapped at the Equator or along lateral vertical boundaries such as coastlines or mountain ranges. The existence of the Kelvin wave relies on (1) gravity and stable stratification for sustaining a gravitational oscillation, (2) significant Coriolis acceleration, and (3) the presence of vertical boundaries or the Equator. An important feature of the Kelvin wave is its unidirectional propagation. The Kelvin wave moves equatorward along a western boundary, poleward along an eastern boundary, and cyclonically around a closed boundary (counterclockwise in the Northern Hemisphere and clockwise in the Southern Hemisphere). The wave amplitude is largest at the boundary and decays exponentially with distance from it. At the Equator, Kelvin waves always propagate eastward, reaching their maximum magnitude at the Equator and decaying exponentially with increasing latitude.

There are two basic types of Kelvin waves: boundary trapped and equatorially trapped. Each type of Kelvin wave may be further subdivided into surface and internal Kelvin waves. Surface, or barotropic, waves penetrate the entire depth of the fluid. Kelvin waves also appear within the stably stratified ocean and atmosphere, and are called internal, or baroclinic, Kelvin waves. Internal Kelvin waves are often found in a layer with large density gradients; the density gradient acts as an interface that allows the existence of internal gravity waves. Examples of such density gradients are the oceanic thermocline (a layer of large vertical temperature gradient separating a shallow layer of warm surface water about 50–200 m deep and a much deeper layer of cold water below) and the lower edge of an atmospheric inversion, a layer in which temperature increases with height. Like gravity waves, Kelvin waves can also propagate vertically in a continuously stratified geophysical fluid.

Atmospheric Kelvin waves play an important role in the adjustment of the tropical atmosphere to convective latent heat release, in the stratospheric quasibiennial oscillation (QBO), and in the generation and maintenance of the Madden–Julian Oscillation (MJO). Oceanic Kelvin waves play a critical role in tidal motion, in the adjustment of the tropical ocean to wind stress forcing, and in generating and sustaining the El Niño Southern Oscillation (ENSO).

Boundary-Trapped Kelvin Waves

Surface Kelvin Waves

The mechanism and properties of the Kelvin wave can be illustrated by considering a horizontally propagating Kelvin

wave in a rotating fluid of uniform finite depth H , where H is small compared to the horizontal extent of the fluid. The fluid has homogeneous density and a free surface, and is confined by a vertical lateral boundary. Such an idealized model is referred to in geophysical fluid dynamics as a shallow water model.

The lateral bounding wall prohibits flow across the boundary, and this absence of transverse motion with respect to the lateral boundary is a defining characteristic of Kelvin waves (Figure 1). Fluid parcels (elements) are constrained to move in a vertical plane parallel to the lateral boundary in the neighborhood of the boundary. Thus, the horizontal longshore (along the boundary) component of the Coriolis force must vanish. Consequently, the wave motion at the lateral boundary, and in any parallel vertical plane, is exactly the same as a hydrostatic gravity wave in a nonrotating system, i.e., the shallow water gravity wave (Figure 1). The wave travels along the boundary with the shallow water gravity wave speed C determined by the square root of the product of the gravitational acceleration (g) and the depth of the fluid, $C = (gH)^{1/2}$. The shape of the wave in the longshore direction is arbitrary and is conserved as the wave travels. This implies that the surface Kelvin wave is nondispersive, and that the wave energy

Figure 1 Northern Hemisphere Kelvin waves on opposite sides of a channel that is wide compared to the Rossby radius. In each vertical plane parallel to the coast, the currents (shown by arrows) are entirely within the plane and are exactly the same as those for a long gravity wave in a nonrotating channel. However, the surface elevation varies exponentially with distance from the coast in order to give a geostrophic balance. This means Kelvin waves move with the coast on their right in the Northern Hemisphere and on their left in the Southern Hemisphere. Reproduced from Gill, A.E., 1982. *Atmosphere–Ocean Dynamics*. Academic Press, New York, NY.

is transmitted at the speed of the shallow water gravity wave. Because the Kelvin wave solution in any vertical plane parallel to the lateral boundary is identical to that of the nonrotating case, the energy of a Kelvin wave is partitioned equally between kinetic energy and potential energy.

A fundamental difference between the Kelvin wave and the two-dimensional gravity wave is that the Kelvin wave can propagate in only one direction, rather than in two opposite directions. This is due to the constraints of the Earth's rotation and the presence of the lateral boundary. Rotation modifies the flow by piling up fluid against the lateral boundary, producing an offshore (normal to the boundary) pressure gradient force associated with the surface elevation. Since offshore motion is prohibited by the presence of the boundary, the offshore pressure gradient force must balance the Coriolis force associated with the longshore flow. For this reason, the motion is referred to as semigeostrophic (i.e., geostrophic balance is reached in only one direction). A direct consequence of this geostrophic balance is the exponential decay of the longshore velocity and surface height with distance from the lateral boundary (Figure 1). The Kelvin wave amplitude is significant only within an e-folding distance of the order of the Rossby radius of deformation (R) from the lateral boundary. This important length scale is defined by the ratio of the gravity wave speed, C , over the absolute value of the Coriolis parameter (f). Over this characteristic distance, the tendency of the gravitational force to flatten the free surface is balanced by the tendency of the Coriolis force to deform the surface. This is possible only for a wave traveling in the direction along which the lateral boundary (where the wave has maximum amplitude) is always on the right in the Northern Hemisphere and on the left in the Southern Hemisphere (Figure 1). Therefore, the effects of rotation and the lateral boundary determine the unidirectional propagation and the trapped behavior of the Kelvin wave.

Internal Kelvin Waves

The horizontally propagating internal, or baroclinic, Kelvin wave behaves in the same manner as the surface wave except that the motion varies with depth. Most frequently, it occurs at a stable interface (or a thin layer with large vertical density gradients) separating two relatively homogeneous layers. For internal Kelvin waves, the pressure gradient force normal to the lateral boundary arises from the tilt of the interface and is balanced by the Coriolis force associated with the vertical differential flow parallel to the boundary. The internal Kelvin wave speed depends on the density difference across the interface and is normally much slower than that of surface Kelvin waves. In the ocean, the typical speed for internal coastal Kelvin waves is of the order of 1 m s^{-1} and the Rossby radius of deformation is of the order of 10 km in the midlatitudes. Evidence for coastal Kelvin wave propagation along the eastern boundary of the Pacific has been observed in coastal sea level and temperature records.

In the atmosphere, boundary-trapped Kelvin waves occur primarily in the form of internal waves. They are often found along the edge of a plateau or a mountain range, such as the coast of South Africa, the west coast of California, and the eastern flank of the Tibetan Plateau. These internal Kelvin

waves are created near a stable inversion layer (often located at the top of the boundary layer) against steep topography. The elevated plateau or mountain range rises above the inversion, forming a lateral boundary for the air of the lower layer. Energy is prevented from escaping vertically by the inversion and laterally by the topography. The maximum disturbance intensity of these waves is found near the coast or plateau and decreases exponentially in intensity away from the coast or plateau. The offshore extent of the waves depends on both the thermal structure and topography. When the topography is steep, the depth of the inversion determines the Rossby radius for the atmospheric Kelvin wave. A typical value for atmospheric internal Kelvin waves is on an order of 1000 km.

Equatorially Trapped Kelvin Waves

Matsuno in 1966 showed that the eastward-propagating Kelvin wave is a possible free solution to the perturbation equations of the shallow water model on an equatorial β -plane (β is the meridional gradient of the Coriolis parameter), provided that the meridional velocity vanishes. This type of wave is called an equatorial Kelvin wave, so named because it is extremely similar in character to coastally trapped Kelvin waves, with the Equator serving as a boundary.

Like the coastal Kelvin wave, the propagation of an equatorial Kelvin wave is unidirectional, i.e., eastward only. In each vertical plane parallel to the equatorial vertical plane, the motion of fluid particles is precisely the same as that in a shallow water gravity wave (Figure 2). The Kelvin wave propagates without dispersion at the speed $C = (gH)^{1/2}$, as for nonrotating long gravity waves. Because the Coriolis parameter changes sign at the Equator, eastward flow occurring on both sides of the Equator would induce equatorward Ekman mass transport, piling up fluid at the Equator and generating a meridional pressure gradient force. In this sense, the Equator acts as a lateral wall. The Earth's rotation links the motion in each latitudinal plane, because momentum conservation in the north-south direction requires a geostrophic balance between the eastward velocity and the meridional pressure gradient force. This geostrophic balance results in the perturbation zonal velocity reaching a maximum on the Equator and decaying with increasing distance from the Equator (Figure 2). This is possible only for eastward-traveling waves. Thus, equatorial Kelvin waves are eastward-propagating and have zonal velocity and pressure perturbations that vary with latitude as Gaussian functions centered on the Equator (Figure 2). The e-folding distance for decay with increasing latitude is given by $Rc = (C/2\beta)^{1/2}$, where $C = (gH)^{1/2}$ is the gravity wave speed and β is the meridional gradient of the Coriolis parameter at the Equator. Rc is called the equatorial Rossby radius of deformation, because of its relationship with the decay scale for the case of constant Coriolis parameter. The same analysis can be applied to baroclinic waves in both atmosphere and ocean, with H being interpreted as the equivalent depth. Typical values of the internal gravity wave speed, C , for the tropical atmosphere are $20\text{--}80 \text{ m s}^{-1}$, giving an equatorial Rossby radius of between 6° and 12° of latitude. For baroclinic ocean waves, appropriate values of C are typically in the range of $2\text{--}3 \text{ m s}^{-1}$, so that the equatorial Rossby radius is $200\text{--}250 \text{ km}$.

Figure 2 The theoretical equatorially trapped Kelvin wave solution to the linear shallow water equations on an equatorial β -plane for a nondimensional zonal wave number 1, which is constructed from the theory of Matsuno (1966). Hatching is for convergence and shading for divergence, with a .6 unit interval between successive levels of hatching or shading, and with the zero divergence contour omitted. Unshaded contours are for geopotential, with a contour interval of .5 units. Negative contours are dashed and the zero contour is omitted. The largest wind vector is 2.3 units, as marked. Reproduced from Wheeler, M., et al. 2000. Large-scale dynamical fields associated with collectively coupled equatorial waves. *Journal of the Atmospheric Sciences* 57(5), 613–640.

Vertically Propagating Kelvin Waves

In general, the Earth's rotation traps planetary-scale gravity waves in the troposphere unless the frequency of the wave is greater than the Coriolis frequency (about $(1 \text{ day})^{-1}$). For this reason, midlatitude synoptic waves are generally unable to penetrate significantly into the stratosphere. However, near the Equator, the dramatic decrease in the Coriolis parameter allows these longer period waves to propagate vertically. Vertically propagating Kelvin waves have been identified in both the equatorial atmosphere and ocean.

Vertically propagating Kelvin waves can be illustrated by considering a continuously stratified fluid with a constant buoyancy frequency in a semiinfinite vertical domain near a lateral boundary or in the vicinity of the Equator. For simplicity, consider a linear equatorial β -plane model. Solutions can be obtained using the normal mode technique by neglecting meridional perturbations. In a vertical section along the Equator, or in any parallel vertical plane, the motion of vertically propagating equatorial Kelvin waves shares the properties of an ordinary vertically propagating gravity wave. A vertical cross section of the perturbation motion, pressure, and temperature structure for vertically propagating Kelvin waves is shown in Figure 3. The local change in temperature is due to adiabatic warming or cooling, so that the temperature

Figure 3 Longitude–height section along the Equator showing pressure, temperature, and wind perturbations for a thermally damped Kelvin wave. Heavy wavy lines indicate material lines; and short blunt arrows show phase propagation. Length of the small thin arrows is proportional to the wave amplitude, which decreases with height owing to damping. The large shaded arrow indicates the net mean flow acceleration owing to the wave stress divergence. Reproduced from Holton, J.R., 1992. *Introduction to Dynamic Meteorology*, third ed. Academic Press, San Diego, CA.

oscillation leads the vertical (zonal) wind and pressure oscillations by a quarter cycle.

Since stratospheric Kelvin waves are forced from below by disturbances in the troposphere, the wave energy propagation must have an upward component. According to theory, Kelvin waves become dispersive in the presence of vertical propagation, and the vertical component of their phase velocity is always opposite to that of their group velocity (the velocity at which the wave energy is transmitted). Thus, the phase velocity must have a downward component. The condition of eastward propagation due to equatorial trapping requires that the vertical wave number be negative. Hence, an eastward and downward-propagating equatorial Kelvin wave has constant phase lines that tilt eastward with height (Figure 3).

Because the variation in zonal wind depends on the pressure gradient force, the highest zonal pressure gradient precedes the largest westerly acceleration by a quarter wavelength, and the zonal wind and pressure waves coincide. This creates an upward flux of wave energy. An individual parcel moves up along the tilted phase line, bringing westerly momentum upward, and moves down, bringing easterly momentum downward. Thus, the Kelvin wave transports westerly momentum upward.

Significance of Kelvin Waves in the Atmosphere and Ocean

Oceanic Kelvin Waves

Kelvin waves are essential in the description of ocean tides. For a deep ocean ($H = 5 \text{ km}$) at 30° N , the Rossby radius for barotropic Kelvin waves is about 3000 km. Continental shelf

regions normally extend about a hundred kilometers seaward; hence, a steep continental slope is practically indistinguishable from a vertical boundary at the scale of the Rossby radius. Thus, a barotropic Kelvin wave extends far from the coast and occupies a substantial fraction of a typical ocean. Much of the energy of tide waves traveling along continents is transmitted in the form of barotropic Kelvin waves with a speed of about 200 m s^{-1} . For instance, along the coast of California more than two-thirds of the semidiurnal and half the diurnal tidal amplitudes can be accounted for by traveling barotropic Kelvin waves. For shallow seas and coastal waters, the Rossby radius is about 200 km. When a Kelvin wave moves through a region in which the fluid depth or the Coriolis parameter varies and the wave energy flux remains constant, the amplitude of the wave varies in proportion to $(f/H)^{1/2}$. Thus, wave amplitude increases when Kelvin waves move into shallow water. In coastal regions, Kelvin waves can also be generated as storm surges are diffracted by vertical boundaries and scattered by irregular coastlines. Variable longshore winds and atmospheric pressure gradients acting on the sea surface are also possible energy sources for oceanic Kelvin waves.

Internal coastal Kelvin waves can be generated by wind-induced, time-dependent coastal upwelling. Coastal upwelling (downwelling) is caused by an Ekman mass flux transported offshore (onshore) and forced by longshore winds. The disturbances can then propagate along the coast as boundary-trapped internal Kelvin waves. Therefore, the amount of upwelling depends not only on local wind forcing but also on the forcing that generated the waves at an earlier time. In a lake, during strong wind forcing, the region of upwelling progresses cyclonically (in the Northern Hemisphere) at the speed of an internal Kelvin wave.

Equatorial Kelvin waves play a critical part in thermocline adjustment. As the equatorial ocean circulation responds to wind stress forcing, equatorial Kelvin waves transmit signals rapidly from the western to the eastern extremities of the ocean basin. Internal Kelvin waves propagating along the thermocline take about 2 months to cross the entire equatorial Pacific. These equatorial Kelvin waves play an essential role in the ENSO cycle. First, they support a positive feedback between the central Pacific zonal wind and eastern Pacific sea surface temperature (SST) anomalies. A westerly wind anomaly excites

Figure 4 Solution for heating symmetric about the Equator in the region $|x| < 2$ for decay factor $\varepsilon = 0.1$. (a) Contours of vertical velocity w (solid contours are 0, 0.3, 0.6, broken contour is -0.1) superimposed on the velocity field for the lower layer. The field is dominated by the upward motion in the heating region where it has approximately the same shape as the heating function. Elsewhere there is subsidence with the same pattern as the pressure field. (b) Contours of perturbation pressure p (contour interval 0.3) which is everywhere negative. There is a trough at the Equator in the easterly regime to the east of the forcing region. On the other hand, the pressure in the westerlies to the west of the forcing region, though depressed, is high relative to its value off the Equator. Two cyclones are found on the northwest and southwest flanks of the forcing region. (c) The meridionally integrated flow showing: (1) stream function contours and (2) perturbation pressure. Note the rising motion in the heating region (where there is a trough) and subsidence elsewhere. Reproduced from Gill, A.E., 1980. Some simple solutions for heat-induced tropical circulation. *Quarterly Journal of the Royal Meteorological Society* 106, 447–462.

downwelling Kelvin waves, which propagate into the eastern Pacific, suppressing the thermocline and causing the SST to rise; this, in turn, enhances the central Pacific westerly wind anomaly by increasing the eastward pressure gradient force in the atmosphere. This positive feedback provides a development mechanism for ENSO SST warming. Second, the cyclonic wind stress curl associated with the central Pacific westerly wind anomaly can induce upwelling oceanic Rossby waves that propagate westward. These waves are eventually reflected at the western ocean boundary, generating upwelling equatorial Kelvin waves, which propagate into the eastern Pacific and offset the warming by enhancing vertical cold advection. This negative feedback provides a mechanism for turning the coupled system to its opposite (La Niña) phase and sustaining the ENSO cycle. In addition, the atmospheric intraseasonal wind forcing continuously generates equatorial Kelvin waves whose nonlinear rectification to the mean state may also contribute to the eastern Pacific warming.

Atmospheric Equatorial Kelvin Waves

The atmospheric equatorial Kelvin wave is one of the critical wave motions in the response of the tropical atmospheric circulation to a heat source (Figure 4). When an imposed heating centered on the Equator is switched on at some initial time, Kelvin waves carry information rapidly eastward, thereby creating easterly trade winds in that region and forming a Walker cell (rising motion over the heat source region and sinking motion to its east) (Figure 4(c)). Internal equatorial Kelvin waves traveling with typical speeds of $20\text{--}80\text{ m s}^{-1}$ are an effective means by which the equatorial atmosphere becomes homogenized in the zonal direction. The easterly winds are in geostrophic equilibrium, so that there is a trough along the Equator, with the winds along the Equator flowing

directly down the pressure gradient (Figure 4). The westward-propagating Rossby wave regime to the west of the forcing region is about one-third the size of the Kelvin wave regime because Rossby waves travel at one-third of the Kelvin wave speed (Figure 4(a)). The equatorial westerlies between the symmetric Rossby waves provide inflow into the heating region, and are in geostrophic equilibrium, so that a relative ridge appears along the Equator (Figure 4(b)). Meanwhile, the flow converges toward the Equator. If atmospheric damping is taken into account, this simple model can largely explain the steady-state atmospheric response to an imposed heat source.

Kelvin and mixed Rossby-gravity waves are the predominant disturbances in the equatorial stratosphere, and play a critical role in the stratospheric circulation through their vertical transport of energy and momentum. Stratospheric Kelvin waves are excited by oscillations in the large-scale convective heating pattern in the troposphere, and are a source of westerly momentum for the QBO (see **Middle Atmosphere**: Quasi-Biennial Oscillation). The QBO is a zonal wind oscillation in the equatorial stratosphere, and propagates downward with a period of about 24–30 months. Figure 5 shows an example of the zonal wind oscillations caused by the passage of Kelvin waves near the Equator. The descent of the westerly phase of the QBO is shown in the figure. At each level, there is an increase of the zonal wind with time. Superposed on this secular trend is a fluctuating Kelvin wave component with a period of about 12 days and a vertical wavelength of about 10–12 km. As vertically propagating Kelvin waves carry westerly momentum upward, they are damped by radiative cooling, small-scale turbulence, and critical level interaction. As the waves are damped, they lose momentum and accelerate the westerly mean flow. The damping depends on the Doppler-shifted wave frequency. As the Doppler-shifted frequency decreases, the vertical

Figure 5 Time–height section of zonal wind at Canton Island (3° S). Isotachs at intervals of 5 m s^{-1} . Westerlies are shaded. Reproduced from Holton, J.R., 1992. Introduction to Dynamic Meteorology, third ed. Academic Press, San Diego, CA. Original courtesy of Wallace, J.M., Kousky, V.E.

component of the group velocity also decreases, and a longer time is available for the wave energy to be damped. Hence, westerly Kelvin waves tend to be damped preferentially in the westerly shear zone where their Doppler-shifted frequencies decrease with height. The associated momentum flux convergence produces westerly acceleration of the mean flow, causing the westerly shear zone to descend. A similar argument is valid for the downward propagation of the easterly phase of the QBO through the action of Rossby-gravity waves.

A peak in the variability of the tropical atmosphere appears in the 30- to 60-day period range, and is known as the MJO. Madden and Julian found that a 30- to 60-day oscillation in zonal winds is in approximate geostrophic balance with varying pressure maxima and minima centered at the Equator. A low-level low-pressure anomaly is accompanied by low-level easterly anomalies. The pressure and zonal wind are out of phase in the upper troposphere. The wave patterns move eastward along the Equator. At the Equator, the meridional winds appear to be insignificant. The amplitude of the oscillation decays with distance away from the Equator. These features are similar to those of internal equatorial Kelvin waves except that the large vertical scale of the MJO implies a faster phase speed than is observed. Arguments involving coupling with equatorial westward-traveling Rossby waves and interaction with the release of latent heat in the

disturbances as well as viscous damping have been invoked to explain the observed slow phase speed.

Introduction

Kinematics, when applied to the atmosphere, refers to the description of both air motion and the motion of patterns describing other properties of air, such as moisture content, temperature, and pressure. This description is without regard to forces and other physical processes that cause the motions. Air motion itself is an important causal factor for many of the pattern changes of the other properties of the air. Daily sequences of weather maps showing horizontal wind flow and the movement of patterns in pressure and temperature dramatize the kinematic perspective of the atmosphere.

This article presents an overview of atmospheric kinematics as follows. First, a brief historical perspective is presented. Then, basic characteristics and descriptors for air motion are reviewed. Finally, examples of the wide range of applications of kinematic analysis of the atmosphere are presented.

History

Studies of the kinematics of air motion date back to the advent of observing system networks for wind which first became available in the nineteenth century over parts of Europe and the United States. Kinematics was applied to early studies of the extratropical cyclone. Historical presentations by Kutzbach in 1979 and Eliassen in 1999 document how the analysis and development of theory for these cyclones depended on the kinematics of the surface wind field. In particular, conflicting theories were resolved by noting whether the dominant surface wind flow was primarily convergent, rotational, or confluent – three of the important basic air motion descriptors of atmospheric kinematics to be discussed later.

Weather map depictions of the atmosphere became common in the twentieth century. Kinematics became a basic analysis perspective not only for wind fields but also for describing the motions of weather map patterns, such as the movement of pressure isobars, and weather fronts. The determination of large-scale vertical motion (a quantity that could not be measured directly) was an important application of kinematics. Using a kinematic method, vertical motion was determined from the horizontal divergence in the observed wind field using a relationship from the continuity of mass equation.

By the middle of the twentieth century, kinematic analysis for the atmosphere had become fully developed. Authors such as Saucier in 1955 and Pettersen in 1956 described a wide range of atmospheric kinematic principles and applications.

Basic Air Motion Properties

Motion Characteristics

The advection (transport) of atmospheric properties by air motion is a fundamental means by which the air motion affects the state of the atmosphere. This advection alone can change conditions at a specific point in space as patterns of fluctuation in the atmosphere are moved past this position. For instance, a west wind in an area where the air temperature is warmer to the west than to the east will tend to increase temperatures in the middle area (Figure 1). The mathematical description of this effect can be expressed as

$$\partial T / \partial t = -u \partial T / \partial x \quad [1]$$

where T is the temperature, t the time, u the air motion speed in the west–east direction, x the distance in the west–east direction, and ∂ the partial derivative operator. The right-hand side quantity is generally referred to as thermal advection. The temperature change, $\partial T / \partial t$, is positive as u is positive and $\partial T / \partial x$ is negative for the conditions described above.

The fact that the air motion, itself, varies in space adds an important characteristic to the advection effect. Namely, the differential in advection effects can change the shape and pattern of the quantity of air being moved at the same time it is being displaced. These effects have been examined most thoroughly for the two-dimensional case, i.e., the horizontal wind field and horizontal distribution of air properties. Significant distortions in horizontal patterns can arise with differential advection acting over sufficiently long durations of time.

The differential advection capabilities of the horizontal wind field can change the horizontal distribution patterns of properties such as temperature, pressure, moisture, or the wind field itself. Spatial variation in a velocity field can be described as the summation of four distinct properties of the wind field. These properties and their effects on an individual element, for example a specified region of water vapor, are summarized below and in Figure 2:

1. *uniform translation*: movement with no change in shape, orientation, or horizontal extent;
2. *rotation*: change in orientation without change in shape or horizontal extent;

Figure 1 Temperature and wind pattern (arrows) that lead to warming at Point A by the advection (transport) process due to the air motion.

Figure 2 Four basic kinematic properties of air motion and the effect of each, respectively, on an element being advected (transported) by the air. Panels (a–d) show uniform translation, rotation, divergence, and deformation, respectively, for horizontal motion. The solid line enclosed area shows the advected element at the initial time and the dashed-line enclosed area shows the element at a slightly later time.

3. *divergence*: change in horizontal extent or area without change of shape and orientation; and
4. *deformation*: change in shape without rotation or change in horizontal extent.

Mathematical definitions of these four properties for the two-dimensional wind field can be derived using a linear Taylor series expansion of the velocity field with reference to the center position of the specified area of interest. Let u_0 and v_0 be the values of the x component (eastward) and y component (northward) of the horizontal velocity at the center point and $u(x, y)$ and $v(x, y)$ be the velocity component values at distances x and y from the center point. Then, the wind field characteristics relevant for each of the four effects, respectively, are:

1. *uniform translation*: movement with speed u_0 in the x direction and v_0 in the y direction;
2. *rotation*: turning defined by the vertical component of vorticity, $\zeta = \partial v / \partial x - \partial u / \partial y$;
3. *divergence*: expansion defined by horizontal divergence, $\delta = \partial u / \partial x + \partial v / \partial y$; and
4. *deformation*: shape distortion at a rate defined by the horizontal component magnitude.

$$|D| = [(\partial u / \partial x - \partial v / \partial y)^2 + (\partial v / \partial x + \partial u / \partial y)^2]^{1/2}$$

Note that ‘vorticity’ referenced in the rotation definition may be described as ‘relative vorticity’ in atmospheric applications where velocities are measured ‘relative’ to the Earth’s surface which itself is turning. Also note that the deformation expression is more complex than the vorticity and divergence expression in that it depends on the position of the coordinates, i.e., the details of deformation effects depend on the orientation of the deformation field. The deformation has two components described in the definition above by the two quantities that are squared inside the square root function.

The basic differential advection characteristics can be generalized for the full three-dimensional wind field. This results in many more scalar descriptors for the motion properties compared to the two-dimensional case presented above. The two-dimensional (horizontal) perspective is sufficient for many atmospheric applications, especially for large-scale motions, such as those depicted in weather maps, where the flow field is predominantly horizontal. This would not be true for small-scale systems such as turbulence near the Earth’s surface, cumulus clouds, and tornadoes. In these cases, vertical motion fluctuations can be as large as those for the horizontal motions.

Motion Descriptors

There are a number of descriptors for air motion that are frequently used in kinematic analysis of the atmosphere. It is useful to define them and to indicate why they are useful and how they relate to the fundamental definition of motion. Air motion is a vector with a direction and magnitude (speed) that alternatively may be described by the components of motion in the directions of the coordinate system. In the three-dimensional atmosphere, an example would be the u , v , and w components in the eastward (x), northward (y), and vertical (z) directions, respectively.

The four distinct properties of the air motion described above (uniform translation, vorticity, divergence, and deformation) are not only important components for the kinematic description but also serve as basic variables for analyzing the dynamics of the system. For large-scale horizontal motions where the vertical vorticity component is generally larger than the horizontal divergence and deformation components, the governing equations of motion can be approximated by equations for the rate of change of the vertical component of vorticity. Divergence has a direct relationship to vertical motion and is often used in descriptions for large-scale airflow to represent vertical motion conditions. Deformation has more limited use as a separate variable. Its most basic application is in relation to analysis for atmospheric frontogenesis, the situation where horizontal variations (gradients) of temperature, or other atmospheric descriptors, are increasing.

Six other descriptors used to characterize air motions in the atmosphere are discussed below.

1. *Streamline*: line parallel to and following along the flow direction in space at a given time. Streamlines give information only on direction of flow, not the speed of flow. The direction taken by smoke coming out of a smokestack will be in the same direction as the streamlines at the time when it comes out. Often streamlines are shown for two-dimensional space.
2. *Isotach*: contour surface connecting positions with the same wind speed. On a two-dimensional chart, isotachs are contour lines which together with streamlines give a complete description of the two-dimensional flow field.
3. *Trajectory*: line following the course of an air parcel element which is moving with the air motion. In general, the trajectory is three-dimensional. Often trajectories are shown for a nearly horizontal two-dimensional space such as the Earth's surface. Trajectories will follow streamlines if flow conditions are steady state. The track taken by a single puff of smoke emitted from a smokestack defines its trajectory.
4. *Streakline*: line connecting the air parcel elements whose trajectories all emanate from a single position in space. The pattern produced by a smokestack that is continually emitting smoke is one example of a streakline.
5. *Streamfunction*: a function in two-dimensional space (e.g., $\psi(x, y)$) whose spatial gradients define the wind flow for nondivergent flow conditions in that space in the following way: $u = -\partial\psi/\partial y$ and $v = \partial\psi/\partial x$. The contours of constant streamfunction, like the streamlines, are parallel to the wind flow. In addition, the gradients of streamfunction value perpendicular to the lines of constant streamfunction define the wind speed. Thus, in a map showing streamfunction contoured at a regular interval, the distance between adjacent contours will be inversely related to the wind speed (Figure 3). For many quasihorizontal, large-scale atmospheric flows, which have negligible horizontal divergence, the streamfunction is sufficient to define the horizontal wind field. The Laplacian of streamfunction defines the associated vertical component of vorticity, ζ , according to the relationship

$$\zeta = \nabla^2\psi = \partial^2\psi/\partial x^2 + \partial^2\psi/\partial y^2 \quad [2]$$

Figure 3 Contours for streamfunction (solid lines) and the associated wind field (arrows) for a two-dimensional and nondivergent flow. The arrows show the direction of flow and have lengths proportional to speed. Streamfunction values of the contours decrease going from the bottom to the top of the chart.

6. *Velocity potential*: a function (e.g., $\chi(x, y, z)$) whose gradients in space define the divergent components of motion. In atmospheric sciences where a two-dimensional formulation is commonly used, the horizontal divergence is defined from $\chi(x, y)$ by the relationships $u_\chi = -\partial\chi/\partial x$ and $v_\chi = -\partial\chi/\partial y$, where u_χ and v_χ refer to the divergent component of velocity in the x and y directions, respectively.
7. *Wind shear*: variations of the wind vector or its components in a given direction. Commonly, this term is used to refer to a lateral wind shear, i.e., a change in speed in a direction perpendicular to the wind direction (Figure 4). Thus for west-to-east wind flow defined by the u component of motion in the x direction, lateral wind shear involves variations in the y direction (north) and z direction (vertical). The presence of wind shear is a factor in many types of flow instability. Wind shears are also representative of both vorticity (rotational) and deformation flow components in the wind.

Figure 4 Example of a lateral wind shear field for straight-line wind flow. The arrows show the (uniform) direction of flow and the arrow length is proportional to the speed.

Applications

Kinematic analysis is used in a wide number of applications to describe conditions in the atmosphere. Several of these are briefly described here.

Describing Pressure Field Patterns

As mentioned earlier, kinematic analysis has been applied to the motion of patterns of pressure, temperature, humidity, etc. describing the atmospheric condition, such as seen in weather map sequences. A common depiction is made for pressure distributions, which relate directly to the horizontal wind for large-scale conditions. Pressure at a constant height (often mean sea level) is used to describe the surface weather systems and winds using lines connecting regions with the same pressure (called isobars). At higher levels in the atmosphere, the horizontal pressure variations are commonly represented by variations of the height where a given pressure is found. In this case, lines of constant height on a surface of fixed pressure (called height contours) are used rather than lines of constant pressure (called isobars) on a surface of fixed height to define the horizontal pressure variations. In the discussion below, these terms are used interchangeably.

The motions of the surface pressure isobars and height contours themselves are due to both movement and amplitude changes of weather systems. Such motion is witnessed in the propagation of high- and low-pressure system centers and their associated isobar patterns in a sequence of daily weather map

Figure 5 Surface pressure isobars (solid lines) for large-scale weather systems for two consecutive times demonstrating the movement and changes of pressure field patterns, a focus of atmospheric kinematics: (a) earlier time and (b) later time. The H and L denote local regions of highest and lowest pressure, respectively. The contour interval is a fixed value, so changes in the number of isobars go along with changes in pressure magnitudes at the H and L positions.

depictions (Figure 5). These motions relate to the pressure tendencies observed by barometers at fixed locations commonly used to indicate pending weather changes. Such pressure tendencies correspond directly to the motions of isobars and the spacing between isobars (magnitude of horizontal pressure gradient).

For large-scale motions, the isobars and height contours themselves have a well-defined relationship to the wind flow in extratropical latitudes according to the ‘geostrophic law’ approximation. Specifically, the horizontal flow tends to be parallel to the isobars and height contours in the direction where, in the Northern Hemisphere, the lower pressure (or height) is to the left facing in the direction of the flow and the higher pressure (or height) is to the right. (Directions are opposite in the Southern Hemisphere.) In addition, the flow speed is inversely proportional to the horizontal pressure gradient, i.e., the distance between adjacent isobars or height contours. This means that the pressure contour patterns have a direct relationship with flow streamlines so that kinematic properties of the airflow itself, such as vorticity and deformation, are suggested by the pressure contour patterns. Near the Earth’s surface frictional effects have a systematic effect on the large-scale wind flow, causing air to have a flow component across isobars from high to low-pressure. This leads to horizontal wind divergence and associated vertical motion when the isobars are curved as around low- and high-pressure centers (Figure 6).

Considerable specialized and descriptive terminology is used for features and their time changes in the large-scale horizontal pressure field patterns not only by scientists but also by weather presenters on radio and television. Commonly used terms include trough, ridge, digging trough, inverted trough, cutoff low, filling low, building ridge, etc. Some of these terms characterize pressure patterns and their changes which are quite useful for describing dynamic as well as kinematic conditions. For instance, in the situation where isobars or height contours run generally east–west with the lower pressures to the north, a ‘trough’ refers to a region of relative minimum in pressure where isobars for various pressure values are displaced southward compared to positions to the east and west. A ‘tilted trough’ means that the longitude of minimum pressure differs according to latitude, so that a line connecting positions for the location of lowest pressure at each latitude ‘tilts’ eastward or westward with latitude (Figure 7). Such tilts for the associated large-scale motion fields imply systematic correlations involving temperature, momentum, and transport processes. These correlations would be expected to result in extratropical storm system development located in the trough area (in the Northern Hemisphere) if the trough is tilted from southwest to northeast (a ‘positive’ tilt) with the reverse for a tilt from southeast to northwest (a ‘negative’ tilt).

Determining Vertical Motion

Vertical motion is a key factor for many aspects of weather, such as cloud development, precipitation, and development of weather systems. Nevertheless, as mentioned before, few direct measurements of vertical motion are available. However, a number of methods exist for estimating large-scale vertical motion. The kinematic method is based on the principle of conservation of mass which provides a direct relationship

Figure 6 Large-scale horizontal wind field (arrows) in the Northern Hemisphere associated with surface pressure isobars (solid lines): (a) without and (b) with surface friction effects, respectively. The H and L denote local regions of highest and lowest pressure, respectively. Note that in Panel (b) with the curved isobars, the horizontal divergence of the wind is more evident. According to the conservation of mass relationship, vertical motion above the surface would be expected in the low- and high-pressure center areas in Panel (b).

Figure 7 Examples of large-scale pressure field patterns (height contours) and associated motion flow direction (arrows) typical in the upper troposphere (Northern Hemisphere) which demonstrate ‘tilted trough’ terminology. Side A: negative tilt trough (a more westward position of the minimum pressure on a latitude line as one goes further north); and side B: positive tilt trough (a more eastward position of the minimum pressure on a latitude line as one goes further north). Heights (pressures) decrease to the north. The motions associated with the positive tilted trough would be expected to produce development of an associated extratropical cyclone.

between the horizontal divergence field and the vertical motion. Recall that horizontal divergence is one of the basic components of the horizontal motion field as discussed earlier.

The atmosphere is a compressible gas so that variations in density must be included in the relationship. For the incompressible case (e.g., like water), a very simple relationship between horizontal divergence and vertical motion exists:

$$\partial w / \partial z = -[\partial u / \partial x + \partial v / \partial y] \quad [3]$$

where w is the vertical motion, z is the height, the other variables are as defined earlier. Integration of this relationship with respect to height provides magnitudes of vertical motion at all levels as long as it is known at one level. To account for the compressibility aspects important for atmospheric weather systems, a density-weighted formula can be used:

$$\partial(\rho w) / \partial z = -[\partial(\rho u) / \partial x + \partial(\rho v) / \partial y] \quad [4]$$

where ρ is density and the variation of ρ in time is assumed to be negligible. This formulation is less easy to use because of the spatial variations in density. In some applications density variations on the right-hand side of the equation can be neglected.

An equivalent formulation of the continuity of mass relationship using pressure instead of height for the vertical coordinate system is often used for determining large-scale vertical motion. In this coordinate system, the vertical motion is represented by the variable ω representing the pressure change following an element of air. In this case the equation becomes

$$\partial \omega / \partial p = -[\partial u / \partial x + \partial v / \partial y] \quad [5]$$

where the derivatives on the right-hand side are evaluated on constant pressure surfaces.

Frontogenesis

Weather ‘fronts’ relate directly to stormy activity and rapid changes. Fronts commonly refer to regions in the large-scale setting where there are maxima in horizontal variations (gradients) for descriptors such as moisture, temperature, and winds in the atmosphere. Horizontal temperature gradients are commonly used to define the fronts and are shown on weather maps as cold, warm, and stationary fronts. Understanding the movement and changes in such fronts is important for describing, understanding, and predicting rapid changes in atmospheric conditions.

An important factor in the formation of large horizontal gradients is the kinematic deformation in the horizontal wind field. Such an increase in gradients occurs when the horizontal deformation flow in the atmosphere is oriented so that the axis of dilatation (expansion) is parallel to the contours of temperature and the axis of confluence (contraction) is perpendicular to the contours of temperature (Figure 8). This results in the contours of different temperature values being brought closer together, signifying an increase in the horizontal temperature gradient. An examination of the existing horizontal temperature distribution and the horizontal deformation distribution in the wind field or as implied from the pressure field can give considerable insight on how existing temperature gradient regions might change.

Figure 8 Horizontal flow deformation field (arrows) and temperature contour (dashed-lines) relationships where the temperature variation (gradient) would be expected to increase in time (a) and decrease in time (b) because the deformation field axis of confluence (shown by a dotted line) is perpendicular or parallel, respectively, to the temperature contours moving them closer together and further apart, respectively. Temperatures are colder at the top side of the diagrams as labeled.

Air Pollution

Air pollution arises from the transport of pollutants from source regions often at or near the Earth's surface. Sources may be obvious point sources like a smokestack or more dispersed sources like automobiles. Temperature differences between the source material and the atmosphere near the source region or density differences due to the pollutants themselves may influence how the pollution propagates. However, much of the propagation will be due to transports by the atmospheric motion. Such transports can be separated into small-scale turbulent motion effects which cause a general dispersion of the pollution over time in all directions and larger-scale motions that provide a more systematic propagation of the pollution. Kinematic analysis can provide useful information on where to expect pollution conditions, especially for the larger-scale motions, and also to determine the source regions for pollution conditions.

Flow trajectories define the path of systematic propagation by air motion. Since most pollution cases involve sources that act over sustained periods of time or even continuously, the distinction between trajectory and streamline is important for understanding the overall lateral spread of pollution from a source area. Namely, the wind flow at any one time is not sufficient information. It is the cumulative effect over time measured by the ensemble of trajectories originating in the pollution source area. The availability of computer models for atmospheric motion makes it possible to determine atmospheric trajectories routinely. It is even possible to determine the source regions of trajectories reaching a given region by looking back in time. This allows for definition of the source regions for air pollution observed in a given area.

Current Weather and Short-Range Prediction

Kinematic analysis of the wind flow is important for understanding current weather conditions and making predictions for the near future, i.e., within 12 h. Dynamical weather prediction models are particularly limited in the first 12 h for predicting clouds and precipitation since these variables are poorly represented in the initial conditions, and it takes a while for the prediction model to recreate existing fields in the

forecast. Extrapolation of initial conditions based on motion transports alone determined by kinematic analysis can provide important information on the atmospheric conditions, especially for moisture, clouds, and precipitation.

Kinematic analysis for horizontal wind flow also provides a direct measure of vertical motion through the kinematic relationship between horizontal divergence and vertical motion (discussed before). Such analysis applied on the small-scale (horizontal dimensions of 100 km or less) is used by forecasters to identify regions of upward vertical motions and thus probably more likely for development of convective precipitation systems in the near future, i.e., several hours. Such analysis is also useful for describing heavy rain situations that have occurred.

Measurement of Winds

A variety of methods are used to measure the horizontal wind flow. Some operate from fixed positions such as surface weather station anemometers and weather vanes that give measurements in a fixed (Eulerian) reference system. Others such as weather balloons, clouds tracked from satellites, and raindrops tracked with Doppler radar provide estimates for tracers presumed to be following the wind flow (a Lagrangian system reference). Cloud tracking techniques for this purpose have the additional challenge of determining the height of the cloud and sorting out situations where the clouds do not move with the horizontal wind such as for the stationary wave clouds seen around mountains. Combining such observations into a single description of the wind flow requires taking into account the distinction between trajectories and streamlines and the differing impacts of space and time averaging.

Analysis and Dynamical Process Studies

Published descriptive summaries of atmospheric circulation features include routinely many of the kinematic horizontal flow descriptors discussed here. For example, the publication *Climate Diagnostics Bulletin* published by the US National Weather Service National Centers for Environmental Prediction provides monthly summaries of many global-scale circulation features. Quantities presented include zonal wind flow (the west-to-east ' u ' component of motion), horizontal flow vectors (streamline direction indicators), and isotachs (speed) for both the lower and upper troposphere along with upper tropospheric level streamfunction, divergent wind, and velocity potential fields. The latter two quantities give an indication of large-scale vertical motion in the atmosphere through the kinematic relationships discussed before.

The kinematic descriptors also are used in studies of the dynamical processes in the atmosphere. The kinematic variables include some more complex than the basic kinematic variables described here. As examples, dynamical studies of large-scale weather systems utilize potential vorticity (a combination of rate of temperature decrease with height and vorticity measures) and Q -vectors (diagnostic variables that relate to vertical motion derived from the equations of motion and thermodynamics as well as the continuity of mass relationships). The study of vortices such as dust devils, tornadoes,

and rotating thunderstorms is facilitated by a kinematic variable called helicity. This variable combines the velocity and three-dimensional vorticity (rotational aspects) of the velocity field.

Conclusions

Atmospheric kinematics embodies the description of movement of air and its descriptors such as moisture content, pressure, and temperature with a focus on the air motion itself. The importance of kinematics has been shown by a sampling of its use in a wide range of applications. In the discussion here, the focus has been on the conceptual aspects of kinematics without dwelling on the mathematics. It should be noted that since air motion is a vector, the complete mathematics for the concepts presented here can involve complicated mathematical expressions.

Introduction

Laboratory experiments represent one of the several approaches employed to gain insight into the processes responsible for natural phenomena. Other approaches include diagnostic studies of observational data, analytic theory, and numerical solutions of the governing equations. Each has strengths and limitations. In concert, they can provide good insight into the mechanisms involved.

Diagnostic studies are useful in the characterization of dynamical properties of observed phenomena such as convection; turbulence; the propagation, growth, and damping of waves; and the time-mean or space-mean circulation. They provide a framework to assess theories and laboratory simulations, which must exhibit essentially the same properties in order to be considered valid. They cannot, however, isolate the roles of controlling parameters (e.g., rotation and differential heating) in bringing about observed phenomena, or provide insight into how things would change if these parameters were altered.

Analytic theory, based on simplified models, is not designed to deal with the full complexity of different phenomena, but rather to determine the roles of the major controlling parameters.

Numerical simulation, using discretized approximations to the full nonlinear governing equations, can treat much more complex systems but is limited in accuracy by the fact that important subgrid-scale phenomena must be parameterized, and by the reality that the solution of the discretized (algebraic) equations departs progressively with time from that of the governing differential equations.

Laboratory experiments, under carefully controlled and reproducible conditions, can be used to verify predictions based on analytic theory and numerical simulation and to discover phenomena that require new theory to explain them. In order to gain insight, it is not desirable to deal with the full complexity of each phenomenon. Moreover, full similarity cannot generally be achieved.

In this article, we select for discussion a few of the many types of experiments that have been employed to understand phenomena in the Earth's atmosphere, oceans, and fluid interior. Examples are chosen that illustrate the interplay of diagnostics, theory, and experiment, and for which regime diagrams have been constructed that map the fluid behavior over a broad range of parameters.

Similarity

In developing a laboratory prototype, one strives to attain similarity in as many ways as possible. An exact model would

be one that had the same geometry as the system to be modeled, but on a smaller scale, and the same governing equations, with the same relative magnitudes of the different terms in these equations. The relative magnitudes are measured by dimensionless numbers, which are ratios of different terms in the governing equations. For example, the ratio of the relative acceleration of a fluid parcel to the Coriolis acceleration in a rotating system leads to the definition of the Rossby number $Ro \equiv |(d\mathbf{V}/dt)|/|2\boldsymbol{\Omega} \times \mathbf{V}|$, where $\mathbf{V}$ is the fluid velocity, t is the time, and $\boldsymbol{\Omega}$ is the angular velocity of the system. If the acceleration is dominated by advection $\mathbf{V} \cdot \nabla \mathbf{V}$, and if V is a characteristic speed of the flow and L a characteristic length scale, the Rossby number can be expressed as $Ro = V/fL$, where f is the Coriolis parameter.

Some dimensionless numbers are arrived at after combining all or several of the governing equations (usually in linearized form) to obtain equations that reveal the relative influences of thermodynamic and mechanical processes. One example is the Rayleigh number $Ra \equiv g\alpha(-\partial T^*/\partial z)H^4/\nu\kappa$, where $-\partial T^*/\partial z$ is the excess of the undisturbed vertical temperature lapse rate over the adiabatic lapse rate in a characteristic depth H of fluid, z is the height, g is the acceleration of gravity, and ν , κ , and α are, respectively, the kinematic viscosity, thermometric conductivity, and coefficient of volume expansion of the fluid due to temperature T . The Rayleigh number measures the ratio of the destabilizing effect of buoyancy to the stabilizing effect of viscous and thermal diffusion.

In geophysical problems, it is usually impossible to construct laboratory analogs with the same geometry as the systems to be modeled. Although some experiments have been done in space vehicles in zero gravity, using electromagnetic forces to simulate gravity normal to a sphere, laboratory experiments on the Earth typically replace the Earth's spherical geometry with cylindrical geometry, in order that gravity be normal to the bottom of the fluid. Moreover, it is not generally possible to achieve the same balances among all terms in the governing equations in the model as in nature. Experimentalists attempt, instead, to model only the balances that are essential to the problem and to explore how the flow changes as the most important parameters are varied.

Vertical Convection between Horizontal Planes (Rayleigh–Bénard Convection)

Convection due to heating at the bottom and cooling at the top of a fluid layer is ubiquitous in the Earth's atmosphere, oceans, and interior. It is also found in the Sun, in other stars, and in the atmospheres and interiors of other planets. The simplest experiment illustrating this phenomenon is accomplished by maintaining the bottom boundary of a liquid at a higher

temperature than the top boundary. In the absence of dissipation, the resulting density increase with height would clearly be unstable, leading to a massive overturning until the more dense fluid is found below the less dense fluid. In the presence of heat conduction and viscosity, however, there is a critical value of the Rayleigh number Ra_c below which convective overturning cannot occur. This value depends on the details of the boundary conditions and the heating arrangement (e.g., constant temperatures or constant heat fluxes at the boundaries), but is always of the order 10^3 . Henri Bénard, who first performed such experiments in 1900, found that, when convection set in, it took the form of polygonal cells (which ultimately became regular hexagons). Later experiments showed that the preferred plan form at instability with most imposed conditions is steady two-dimensional rolls. Today, it is generally accepted that Bénard's cells were produced by surface tension gradients due to temperature variations on the free upper surfaces of very shallow fluids.

At successively larger Rayleigh numbers, the plan form of the convection changes, the details depending on Prandtl number ($Pr = \nu/\kappa$). At low Pr , the transition is from steady rolls to three-dimensional periodic oscillations. At high Pr , there is an intermediate range of Ra in which steady three-dimensional cells are observed. At sufficiently large Ra , the periodic oscillations give way to turbulent convection.

Figure 1 shows patterns and the associated circulation that can arise in cellular convection. Figure 2 is a regime diagram covering a broad range of Ra and Pr . Below Ra_c the vertical heat flux $\mathcal{H}$ is accomplished by heat conduction. With increasing Ra above this transition, $\mathcal{H}$ (accomplished primarily by convection) increases with Ra at fixed Pr , with jumps in the rate of increase at each successive transition. At high Rayleigh numbers, within the turbulence regime, convective plumes tilt with height and transfer momentum between the lower and upper portions of the fluid by means of Reynolds stresses, thereby creating and maintaining a steady large-scale circulation of the fluid. Incorporation of this mechanism into the cloud parameterization in one global numerical prediction model led to the correction of systematic errors in the predicted tropical wind field. At very high Ra , the plumes form clusters that exhibit systematic horizontal drift.

Much theoretical work has been done on the convection problem, beginning with the linear theory of Lord Rayleigh in 1916. The theory establishes that the only parameter controlling the onset of convection is Ra , and that the cell diameters at the onset of convection, which are controlled by the buoyancy and dissipative scales, are about twice the depth of the convecting layer. Laboratory experiments confirm the predicted values of Ra_c and the cell size.

Weakly nonlinear theory has been employed to investigate the stability of each of the possible plan forms allowed by the linear theory. Consistent with the results of laboratory experiments, the solutions show that only two-dimensional rolls are stable to small disturbances just above the critical Rayleigh number Ra_c in the absence of vertical asymmetries. Hexagonal cells become the preferred plan form in the presence of such asymmetries.

It is known from both theory and experiment that if horizontal flow is superimposed, the convection becomes aligned in rolls in the direction of the shear. If rotation is

Figure 1 (a) Plan view of convection cells generated by lowering a cylinder containing a high Prandtl number fluid into a larger container of warm fluid. The irregular polygonal plan form is due to the changing mean temperature of the convecting fluid. (b) Vertical cross section depicting broad-scale downward motion along the cell boundaries and upward and outward motions in the interiors of the cells. Experiment by the author, Geophysical Fluid Dynamics Institute, Florida State University.

superimposed, the horizontal dimensions of the convection cells shrink.

In the Earth's atmosphere, cloud patterns give evidence of turbulent convection, clusters, two-dimensional roll convection, and three-dimensional cellular convection under different conditions. Behind maritime cold fronts, convection has been observed in the form of both open and closed cells (Figure 3), the former having upward motion at the cell boundaries and downward motion in the centers, and the latter the reverse circulation. These observations have sparked further experiments and theory that, although highly idealized, seem to have relevance to the observed cloud patterns. Weakly nonlinear theory predicts that three-dimensional open and closed hexagons, rather than rolls, are stable when the mean vertical motion is downward or upward, respectively. Laboratory experiments confirm the existence of these plan forms under the same circumstances. The theory and experiments do not, however, exhibit the aspect ratio observed in the atmosphere,

Figure 2 Regime diagram depicting the dependence of plan form and time dependence on Ra and Pr when the top and bottom boundaries are rigid and maintained at different temperatures. Symbols: $\circ$ steady cellular flow; $\bullet$, time-dependent cellular flow; $\blacksquare$, cells and transient bubbles (transitional); $\square$, transient bubbles; $\sim$, large-scale flow with tilted plumes; and $*$, heat flux transitions. Large-scale flow generation in turbulent convection. *Proceedings of the National Academy of Sciences of the USA* 78: 1981–1985.

where the horizontal scales are from 10 to 50 times the depth of the convecting layer. Clouds are formed by the release of latent heat of condensation, a complication not dealt with in Rayleigh–Bénard convection. More recent experiments

Figure 3 Section of Air Force DAPP satellite photograph (22.30 GMT 4 April 1973) of convective clouds, centered near 30° N and 61° W, showing open cells in a region of large-scale downward motion and closed cells in a region of large-scale upward motion. The region is roughly 500 km on a side. Reproduced from Shaugnessy, J.E., Wann, T.C., 1973. Picture of the month-frontal rope in North Pacific. *Monthly Weather Review* 101: 774–77. demonstrate that large cell sizes can be realized by simulating the release of latent heat of condensation in clouds that form in an otherwise stably stratified atmosphere.

In the ocean, the water density is controlled by both temperature and salinity, and thermal diffusion is much more rapid than salt diffusion. Convection under these circumstances is controlled by four dimensionless parameters, Ra , Pr (both defined earlier), the ratio of the diffusivities of salt and temperature $\tau = \kappa_s/\kappa (<1)$, and the salinity Rayleigh number $Ra_s = g\gamma(\partial S/\partial z)H^4/\nu\kappa$. Here γ is the coefficient of volume expansion of the fluid due to salt and S is the salt concentration. When $\partial S/\partial z < 0$ and $\partial T/\partial z > 0$, the density gradients due to salt and temperature are both stably stratified, and so no instability is possible. When $\partial S/\partial z > 0$ and $\partial T/\partial z < 0$, both gradients are unstably stratified, and convective instability is observed. When either $\partial S/\partial z > 0$ and $\partial T/\partial z > 0$, or $\partial S/\partial z < 0$ and $\partial T/\partial z < 0$, double diffusive instabilities are possible. Such instabilities occur when the net density stratification is stable, but either the temperature is stably stratified and the salt is unstably stratified, or vice versa.

Theory and experiment confirm that when warm, salty water lies over cold, freshwater, with a net stable density stratification, thin ‘salt fingers’ develop for sufficiently large positive Ra_s (unstable) and small negative Ra (stable), with rising fingers of cold, freshwater and sinking fingers of warm, salty water. For very small negative Ra , the salt fingers become unstable and, below a comparatively thin layer, are replaced by a well-mixed convection layer. If the fluid is sufficiently deep, another salt finger layer forms below the well-mixed layer. Within a range of values of the controlling parameters, reflecting, in particular, small negative Ra and deepwater, the instability takes the form of a number of convecting layers bounded above and below by comparatively thin salt finger

Figure 4 Plume convection produced by maintaining a reservoir of low-density fluid (water) below a more dense, highly viscous fluid (corn syrup). Seen here are two thermals and one ‘starting plume.’ The thermals entrain more dense fluid and decelerate. The plume entrains buoyant fluid from the thin trailing filament leading back to the source and accelerates upward. layers. Evidence of such phenomena has been found in the ocean (e.g., in the Mediterranean outflow).

When cold, freshwater lies above warm, salty water, with a net stable density stratification, theory and experiment show that oscillatory instability takes place for sufficiently large positive Ra and sufficiently small negative Ra_s . Once again, layering occurs in sufficiently deep fluids, with well-mixed convective layers bounded above and below by stably stratified diffusive layers. Evidence of this phenomenon has been found below an Arctic ice island, as well as in Antarctic lake Vanda and in other lakes, in which warm seawater from old intrusions is found below cold, fresh lake water.

In the Earth’s mantle, convection is shaped by the temperature dependence of the viscosity of the convecting material. The mantle behaves like an extremely viscous, low thermal conductivity fluid. Internal heating, accompanied by cooling at the surface, creates global-scale convection, resulting in the motions of continents. Moreover, the core heats the lowest layer of the mantle, providing buoyancy and lowering the viscosity locally. Evidence suggests that convection from this source, under very high Rayleigh numbers, takes the form of narrow plumes which, upon reaching the surface, form volcanic chain islands (e.g., the Hawaiian islands), among other features. An example of plume convection modeled in the laboratory is shown in Figure 4.

In the Earth’s fluid core, rotation and electromagnetic (Lorentz) forces play important roles, and the four dimensionless parameters needed to study convection under such influences are the Rayleigh number, the Prandtl number, the Taylor number (the square of the ratio of the Coriolis to the viscous force), and the Elsasser number (the ratio of the magnetic body force to the Coriolis force). Rotation renders the motions nearly two-dimensional in planes normal to the angular velocity Ω , which is not parallel to gravity, and tends to make the cells narrower than they would be in its absence. Electromagnetic forces tend to make the cells wider. Buoyancy

is created in part by thermal effects and in part by compositional changes (solidification of iron and nickel, leaving a buoyant residual liquid at the boundary with the inner core). Convection takes place in a geometry of variable depth owing to the alignment of the convection cells within the spherical annulus. Modeling of all these effects in one laboratory experiment would be very complicated and is probably not possible. Separate experiments modeling thermal convection in a self-gravitating sphere or annulus, thermal convection under the simultaneous influence of rotation and a magnetic field, and compositional convection show qualitative agreement with theory and numerical simulation, but much of this work has not approached the parameter range of the core.

Sloping Convection in Rotating, Laterally Heated Fluids

Pioneering experiments by Dave Fultz and Raymond Hide beginning around 1950 demonstrated that it is possible to simulate basic features of the general atmospheric circulation, including the jet stream and the growth and propagation of midlatitude, synoptic-scale ($L \sim 1000$ km) baroclinic waves. In these experiments, a liquid contained in an upright cylinder or cylindrical annulus is rotated about the axis of the cylinder, heated at the outer wall and cooled either at the center or at the inner wall. Differential heating establishes a radial temperature gradient, analogous to the meridional temperature gradient in the atmosphere. Overturnings create a stable vertical density stratification with Brunt–Vaisala (buoyancy) frequency N . Two main dimensionless parameters control the instability and the scale of the baroclinic waves: the Burger number $B \equiv N^2 H^2 / f^2 L^2$ (which measures the competition between stratification and rotation in determining the baroclinic wave scale) and the Taylor number $Ta \equiv |2\Omega \times \mathbf{V}|^2 / \nu \nabla^2 \mathbf{V}|^2$. Here, f is the Coriolis parameter and $N^2 \equiv g\alpha/\partial T \partial z > 0$. The growth rate of the disturbances is proportional to the ratio of the destabilizing

effect of vertical shear to the stabilizing effect of stratification $|\partial V/\partial z|/N$, the square of which is the inverse of the Richardson number. While fluid motions in the cylinder (or 'dishpan') experiments look more like those seen on upper tropospheric weather maps, the more regular wave patterns in the annulus experiments possess the same essential ingredients and are easier to interpret.

Figure 5 shows the streamlines, isotherms, and vertical velocity contours corresponding to a four-wave pattern in an annulus experiment. The relationships among these variables are similar to those in midlatitude developing baroclinic waves and confirm the predictions of analytic theory. Baroclinic growth is achieved by the rising of warm fluid downstream of the troughs and the sinking of cold fluid downstream of the ridges in the stream field. Away from the boundaries, the motions are quasigeostrophic and hydrostatic, implying thermal wind balance and the existence of a jet stream above the strongest temperature gradients.

The slope of the azimuthal mean potential temperature surfaces in the radial plane is such that the coldest fluid is found at the bottom near the cold source and the warmest fluid at the top near the heat source. A parcel stability argument reveals that instability can take place only if fluid parcels are displaced within the angle between the geopotentials and the potential temperature surfaces (called the Eady angle, after the scientist who elucidated this in his 1949 theory of baroclinic instability). According to linear theory, this can take place only at horizontal scales larger than a critical value that depends on

Figure 5 Plan view of streamlines (solid curves), isotherms (dashed curves), and vertical velocity contours (dotted curves with shading for upward motion) at mid-depth in an annulus experiment. The inner and outer cylinders are held at uniformly cold and warm temperatures, respectively. The annulus is rotated counterclockwise. The pattern travels counterclockwise relative to the annulus. A meandering jet stream, following the most closely spaced streamlines, flows counterclockwise through the pattern. Reproduced from Pfeffer, R.L., Buzyna, G., Fowles, W.W., 1974. Synoptic features and energetics of wave amplitude vacillation. *Journal of the Atmospheric Sciences* 31: 622–645.

B . Shorter waves have parcel motions outside the Eady angle. The fastest growing waves are those for which the parcel motions follow the bisector of this angle. The scale of these waves is $L \sim \lambda = NH/f$ (called the Rossby radius of deformation), corresponding to $B \sim 1$. Longer and shorter waves have slower growth rates because their parcel paths have steeper or less steep slopes.

Figure 6 is a sketch of the regime diagram showing the various wave scales and forms of time dependence observed in annulus experiments. The use of the thermal Rossby number $Ro_T \equiv g\alpha H \Delta T / 4\Omega^2 \Delta R$ (in which the annular gap width ΔR is taken as the length scale and the imposed thermal wind as the velocity scale) reflects the fact that the imposed temperature contrast ΔT controls both the Burger and Richardson numbers.

Outside the curve containing the baroclinic wave regime, the motions are axisymmetric, resembling a Hadley cell with rising and sinking motions near the warm and cold walls, respectively, and fluid spiraling inward in the upper layer and outward in the lower layer. The cutoff of wave instability at large Ro_T is due to the fact that the preferred wave scale for instability is larger than that which can fit within the annulus. The cutoffs at small Ta and Ro_T are due to the dominance of dissipation for small wave scales and/or rotation rates. Within the regular wave regime, the observed wave scales correspond to the predicted value λ , becoming smaller as ΔT is decreased and/or Ω is increased. At lower ΔT (i.e., smaller N^2) and higher Ω , where nonlinearity becomes important in the more irregular flow, the observed scales are generally larger than predicted. Two kinds of time dependence are observed in these experiments: amplitude and structural vacillation.

Amplitude vacillation is a nearly periodic growth and decay of waves (Figure 7(a)–(d)). Axisymmetric overturnings near

Figure 6 Sketch of the regime diagram for baroclinic flow in an annulus with gap width twice the fluid depth, depicting the most probable wave scales and time dependence as a function of Ro_T and Ta at $Pr = 21$. The upper shaded region shows where amplitude vacillation is most prevalent. The unshaded region immediately below it indicates where structural vacillation is most common. The details differ with aspect ratio and Prandtl number.

Figure 7 (a,b) Upper-level wave patterns and (c,d) mid-depth temperature fields in a thermally driven rotating laboratory experiment, depicting minimum and maximum wave amplitudes at opposite phases of an amplitude vacillation cycle. (e,f) 500 hPa height charts depicting opposite phases of an atmospheric 'index cycle.' Reproduced from Pfeffer, R.L., Chang, Y., 1967. Two kinds of vacillation in rotating laboratory experiments. *Monthly Weather Review* 95: 75–82.

the side walls set up large temperature gradients across the middle of the annular gap. Baroclinic instability sets in, leading to explosive wave growth. The waves transport heat across the annular gap and induce a thermally indirect Ferrel cell between the thermally direct meridional cells near the walls. The heat transport is so great that it reduces the horizontal temperature gradient below the critical value needed to overcome dissipative effects, and the waves die out. When the waves become sufficiently weak, axisymmetric overturnings reestablish the radial temperature gradient and the cycle begins anew. Although not periodic, striking cases of a similar process of hemispheric baroclinic wave growth and decay in middle latitudes in winter have been observed in the Earth's atmosphere (Figure 7(e) and (f)).

Structural vacillation is characterized by time-dependent changes in the wave shapes with negligible changes in wave amplitude. As Ro_T decreased and Ta is increased, this form of vacillation first appears as a weak, almost periodic, oscillation. In some experiments, it manifests itself as a periodic tilting of the troughs and ridges such that they transport angular momentum first inward and then outward (Figure 8). In others it manifests itself as an energy oscillation in the radial direction. With further decreases of Ro_T and increases of Ta , the oscillations become modulated and intermittent in time, finally giving way to fully developed geostrophic turbulence. There is good evidence to suggest that structural vacillation represents a form of low-order deterministic chaotic behavior, with the order increasing as one moves toward the region of geostrophic turbulence.

Figure 8 A sequence of flow patterns depicting tilted trough vacillation in a thermally driven rotating annulus of fluid. Courtesy of Professor Fultz, D., University of Chicago.

In addition to the two forms of vacillation, wave dispersion has been observed near the boundaries between wave numbers. In such experiments, two, and sometimes three, adjacent wave numbers are observed, with phase speeds that increase with decreasing scale. It has been speculated that this phenomenon is associated with the slope of the free surface due to rotation, which can act in part like the variation of the Coriolis parameter in the atmosphere, although the wave speed varies linearly with scale rather than quadratically as in the formula for Rossby waves in the atmosphere.

Variations of the annulus experiment have been used to study other influences that affect atmospheric behavior. Among these are bottom topography, land–sea temperature variations, cyclic variations of the imposed temperature contrast (simulating seasonal forcing), and the effect of internal heating in the atmospheres of the major planets on the formation and maintenance of large detached vortices (e.g., Jupiter’s Great Red Spot and related features on Saturn and Neptune). Additional studies of baroclinic fluid behavior have been performed with two homogeneous, incompressible fluids driven by a differentially rotating lid. Here the baroclinicity is concentrated at the interface between the two fluids. Other experiments designed to account for detached vortices have been performed with mechanically driven, rotating barotropic fluids at high Reynolds numbers (the ratio of advection to viscous forces), high Taylor numbers, and low Rossby numbers. Such experiments have also been used to study the properties and stability of the Earth’s stratospheric polar night jet.

One important property of synoptic-scale waves in the atmosphere that has not yet been successfully modeled is the meridional and vertical propagation of such waves, made possible by the presence of a background potential vorticity gradient, the absence of lateral walls, and the unlimited upward extent of the atmosphere. Unlike atmospheric waves, annulus waves are trapped radially and vertically. Innovative experiments attempting to address some of these issues have not yet borne fruit.

Other Experiments

Numerous other geophysical fluid dynamics experiments have been conducted to illustrate fundamental theorems or explain observed phenomena: for example, the Taylor–Proudman theorem (which states that rapid rotation characterized by small Ro and large Ta makes the flow invariant in the direction of Ω); Kelvin–Helmholtz instability (instability generated by a sufficiently large velocity shear across the interface between a lower density fluid and an overlying higher density fluid); axisymmetric inertial instability (the instability of a circular flow when the square of the angular momentum decreases outward and Ta exceeds a critical value: Figure 9); various routes to chaos as a control parameter, such as rotation, are increased; and critical layer absorption (the absorption of neutral linear waves near a surface along which their phase speeds in the direction of the background flow equal the background flow speed). Kelvin–Helmholtz instability is responsible for the formation of billow clouds and wind-driven water waves. Critical

layer absorption plays a crucial role in the quasibiennial oscillation in the equatorial stratosphere.

Other experiments model phenomena such as topographic waves in stratified fluids, penetrative convection in the atmosphere (where tropospheric convection penetrates into the stably stratified stratosphere), and the strong boundary currents found along the western shores of most oceans (e.g., the Gulf Stream, the Kuroshio Current, and the Brazil Current).

Penetrative convection has been modeled by making use of the property that the maximum density of water occurs around 4°C. If the bottom of a container of water is maintained at 0°C, by placing it in contact with a block of ice, and the top is maintained at a temperature well above 4°C, the layer below the 4°C isotherm will have an unstable density stratification, which will lead to convection, and the layer above will have a stable density stratification.

Western boundary currents have been modeled in a rotating cylinder of fluid in which the base is a sloping plane that creates variable depth. It is readily shown that, in an unstratified fluid, the variable depth has the same effect on the flow as the latitudinal variation of the Coriolis parameter has on the

Figure 9 Taylor vortices in a tall cylinder of fluid produced by bringing the fluid into solid rotation and then stopping the rotation. The fluid near the wall slows down while that away from the wall continues to spin, creating an unstable velocity profile. Courtesy of Kung, R., and the author, Geophysical Fluid Dynamics Institute, Florida State University.

atmosphere and the ocean. Experiments and theory confirm that this is the crucial ingredient in the formation of western boundary currents.

Although the present article has by no means covered all types of geophysical fluid dynamics experiments that have been performed, it should give the reader sufficient familiarity with the type of research that is done and the factors that are considered when designing such experiments.

Synopsis

The Eulerian and Lagrangian formulations of fluid mechanics are reviewed, and applications to atmosphere–ocean dynamics are presented. Numerical schemes based on the Lagrangian formulation are discussed.

Introduction

In meteorology and oceanography, we regard our fluid as a continuum – a continuous distribution of mass in space. In so doing, the atomic or molecular nature of the fluid is neglected and this implies that any small volume element is always supposed to be sufficiently large so that it still contains a huge number of molecules. Accordingly, when we speak of an infinitesimal volume element – or a fluid ‘parcel’ – we mean that it is small compared with the volume of the system but still sufficiently large to contain very many molecules.

The adoption of the continuum description is the first step toward specifying how we solve the fundamental problem of the science of kinematics for our fluid; i.e., the specification of suitable methods for describing and analyzing fluid motions. The problem of kinematics, for any given physical system, should be distinguished from that of dynamics, which is concerned with determining the state and/or motion of the system at any instant. It is a common practice to refer to the combined science of kinematics and dynamics as mechanics.

There are two common descriptions of continuum motion (both due originally to Leonhard Euler (1707–83)). In the first method, known as the Lagrangian method, we fix our attention directly on the fluid parcels and study their motion through space. Unless otherwise stated, we shall consider motions in a three-dimensional space. The independent variables are a set of particle labels $\mathbf{a} = (a, b, c)$ and time t . The dependent variables are the coordinates

$$\mathbf{x}(\mathbf{a}, t) = (x(\mathbf{a}, t), y(\mathbf{a}, t), z(\mathbf{a}, t)) \quad [1]$$

of the fluid parcel identified by (a, b, c) . At any given time there is a one-to-one correspondence between the coordinate systems $\mathbf{a}$ and $\mathbf{x}(\mathbf{a}, t)$. We assume that each fluid parcel, which really refers to an imaginary piece of the continuum, is uniquely defined by values of the labels $\mathbf{a}$ for all time. If $\mathbf{x}$ is a suitably differentiable function of its arguments, then the velocity of a parcel is given by $\mathbf{v} = (\partial \mathbf{x} / \partial t)_{\mathbf{a}} = (u, v, w)$ and the acceleration by $(\partial^2 \mathbf{x} / \partial t^2)_{\mathbf{a}}$, where the subscript $\mathbf{a}$ means that the time derivative is evaluated on a parcel (a constant value of $\mathbf{a}$). (In conventional point-particle mechanics, we are accustomed to assigning a position vector, $\mathbf{r}_i$ say, to the i th particle; the continuous label $\mathbf{a}$ in fluid mechanics is the generalization of the discrete label i .) Lagrangian mechanics is the basis for many important conceptual models of fluid flow. In the second method, known as the Eulerian method, we fix our attention on a region of space and study the motion of fluid relative to

that region. That is, the independent variables are the space coordinates $\mathbf{x} = (x, y, z)$ and time t , and the dependent variables are most commonly taken to be the velocity $\mathbf{v}(\mathbf{x}, t)$, the mass density $\rho(\mathbf{x}, t)$, and the pressure $p(\mathbf{x}, t)$. From the density and pressure all other thermodynamic quantities can be determined, provided the equation of state is known.

The time derivative of an arbitrary quantity $A(\mathbf{a}, t) = A(\mathbf{x}(\mathbf{a}, t), t)$ (where we have used the same symbol to denote two different functions) measured in the two descriptions is related by the chain rule

$$\begin{aligned} \left. \frac{\partial A}{\partial t} \right|_{\mathbf{a}} &= \left. \frac{\partial A}{\partial t} \right|_{\mathbf{x}} + \frac{\partial \mathbf{x}}{\partial t} \cdot \frac{\partial A}{\partial \mathbf{x}} \\ &= \left. \frac{\partial A}{\partial t} \right|_{\mathbf{x}} + u \left. \frac{\partial A}{\partial x} \right|_{y, z, t} + v \left. \frac{\partial A}{\partial y} \right|_{x, z, t} + w \left. \frac{\partial A}{\partial z} \right|_{x, y, t} \equiv \frac{DA}{Dt} \end{aligned} \quad [2]$$

which illustrates the relationship between the familiar material or substantial derivative, D/Dt , and $(\partial/\partial t)_{\mathbf{a}}$. The relationship $(\partial/\partial t)_{\mathbf{a}} = D/Dt$ tells us why the material derivative is often referred to as the ‘derivative following a parcel.’

The Lagrangian description of fluid kinematics and dynamics, and related topics, are the subject of this article. The Eulerian description is adopted by most textbooks, but there are many fundamental principles in fluid dynamics that are inherently Lagrangian in nature. To illustrate this point, consider the continuity equation in Eulerian form

$$\left. \frac{\partial \rho}{\partial t} \right|_{\mathbf{x}} + \nabla \cdot (\rho \mathbf{v}) = 0 \quad [3]$$

where, unless otherwise stated, ∇ is the usual gradient operator in three-dimensional space. This familiar equation arises from the requirement that fixed volumes in particle-label space always contain the same mass. That is, if we assign labeling coordinates so that $\mathbf{x}(\mathbf{a}, 0) \equiv \mathbf{a}$ at some initial time $t = 0$, then the mass contained in the small volume $d^3 \mathbf{x}(\mathbf{a}, 0)$ of fluid at $\mathbf{x}(\mathbf{a}, 0)$ is given by $\rho(\mathbf{x}(\mathbf{a}, 0), 0) d^3 \mathbf{x}(\mathbf{a}, 0) = \rho(\mathbf{a}, 0) d^3 \mathbf{a}$. This defines the density, ρ , which we may consider as either a function of Lagrangian labels, $\mathbf{a}$, or Eulerian positions, $\mathbf{x}$. At a later time t , we must have $\rho(\mathbf{x}(\mathbf{a}, t), t) d^3 \mathbf{x}(\mathbf{a}, t) = \rho(\mathbf{a}, 0) d^3 \mathbf{a}$. If we define the specific volume, α , as the Jacobian

$$\alpha \equiv \frac{\partial(\mathbf{x})}{\partial(\mathbf{a})} \quad [4]$$

then the conservation of mass is given by $\rho(\mathbf{x}(\mathbf{a}, t), t) \alpha = \rho(\mathbf{a}, 0)$. For an incompressible fluid, we have $\alpha = 1$ (which corresponds to $\nabla \cdot \mathbf{v} = 0$ in the Eulerian description). It is now possible to

show that $(\partial\alpha/\partial t)_a = \alpha \nabla \cdot \mathbf{v}$, which in turn can be expressed in the form of eqn [3].

Variational Principles and Conservation Laws

In writing down variational principles for fluid systems, one is immediately faced with the choice of adopting either Lagrangian or Eulerian kinematics. Occasionally, it is convenient to change between these representations when performing calculations. In this section we shall review one of the most important features of the Lagrangian description: a connection between an invariant property of this representation and the conservation of a meteorologically significant quantity, potential vorticity.

Hamilton's Principle and Noether's Theorem

We begin by discussing a finite-dimensional problem. Consider a system of n point-particles, with masses $m_i (i = 1, \dots, n)$ and locations $\mathbf{x}_i(t)$, moving under the influence of some potential $V(\mathbf{x}_i)$. Newton's second law of motion for such a system is

$$m_i \frac{d^2 \mathbf{x}_i}{dt^2} + \frac{\partial V}{\partial \mathbf{x}_i} = 0 \quad [5]$$

Hamilton's principle is a variational principle equivalent to Newton's second law, and it states that the action

$$S \equiv \int_{t_0}^{t_1} L dt \quad [6]$$

is stationary, where the Lagrangian $L(\mathbf{x}, \dot{\mathbf{x}}) \equiv T - V$ is the difference between the kinetic energy T and the potential energy V of the system. Hamilton's principle thus states that the variation of the action eqn [6] vanishes for arbitrary, independent variations $\delta \mathbf{x}_i(t)$ that vanish at t_1 and t_0 . Since $\delta \mathbf{x}_i(t_1) = \delta \mathbf{x}_i(t_0) = 0$, we have

$$\int_{t_0}^{t_1} \left[-\frac{d}{dt} \left(\frac{\partial L}{\partial \dot{\mathbf{x}}_i} \right) + \frac{\partial L}{\partial \mathbf{x}_i} \right] \cdot \delta \mathbf{x}_i dt = 0 \quad [7]$$

for all i , where the overdot denotes d/dt . Newton's law follows as a consequence of the arbitrariness of $\delta \mathbf{x}_i(t)$, and the specific form eqn [5] follows from the functional dependence of the potential energy V on $\mathbf{x}_i$ alone, and the usual expression for the kinetic energy

$$T = \frac{1}{2} \sum_{i=1}^n m_i \dot{\mathbf{x}}_i \cdot \dot{\mathbf{x}}_i \quad [8]$$

There is a fundamental connection between certain invariant properties of Lagrangians and the conservation laws for dynamical systems. This connection is embodied in Noether's theorem, which requires considerable expertise in group theory to understand completely. We shall therefore restrict ourselves to a didactic description. Noether's theorem applies to the equations that arise from variational principle like Hamilton's principle. According to *Noether's theorem* (1918), if a variational principle is invariant to a continuous transformation of its dependent and independent variables,

then the equations arising from the variational principle possess a conservation law.

Example. Let us assume that a system has kinetic energy of the form eqn [8], but the potential is independent of x (but still dependent on y and z , say). Therefore the Lagrangian is invariant with respect to small variations in x . The integrand of eqn [7], the so-called Euler–Lagrange equation,

$$\frac{d}{dt} \left(\frac{\partial L}{\partial \dot{x}} \right) - \frac{\partial L}{\partial x} = 0 \quad [9]$$

then yields, assuming independence of x ,

$$\frac{\partial L}{\partial x} = 0 \Rightarrow \frac{d}{dt} \left(\frac{\partial L}{\partial \dot{x}} \right) = 0$$

This is the statement that the x -component of momentum, $m\dot{x}$, is conserved.

Application to Fluid Mechanics: Theorems of Ertel and Kelvin

The fundamental meteorological-cum-oceanographic principle of the conservation of potential vorticity can be traced to the invariance of variational principles for hydrodynamical flows under certain variations of the particle labels, $\delta \mathbf{a}$.

Let $\mathbf{x}(\mathbf{a}, t)$ be the location of the fluid particle identified by labeling coordinates $\mathbf{a} = (a, b, c)$ at time t . The Lagrangian for a perfect fluid is

$$\mathcal{L} = \int d^3 \mathbf{a} \left[\frac{1}{2} \dot{\mathbf{x}}^2 - E(\alpha, S(\mathbf{a})) \right] \quad [10]$$

where the internal energy $E(\alpha, S)$ is a prescribed thermodynamic function of the specific volume, α , and the specific entropy, $S(\mathbf{a})$. The entropy is a Lagrangian conserved quantity. The integration over a measure in particle-label space, $\int d^3 \mathbf{a}$, replaces the discrete sum $\sum_i$, and the overdot is the time derivative $(\partial/\partial t)_a$.

Hamilton's principle states that

$$\delta \int \mathcal{L} dt = 0$$

where δ stands for arbitrary independent variations $\delta \mathbf{x}(\mathbf{a}, t)$, and implies

$$\ddot{\mathbf{x}} + \alpha \nabla p = 0 \quad [11]$$

where $p = -\partial E / \partial \alpha$ is the usual thermodynamic equation relating pressure to internal energy and it may be considered the equation of state. Equation [11] is the momentum balance for a perfect fluid.

The Lagrangian is unaffected by particle-label variations $\delta \mathbf{a}(\mathbf{x}, t)$ that leave the density and entropy unchanged. For the purposes of the following calculation, we shall assume that the particle labels enter only through the specific volume, which is equivalent to the assertion that the fluid is homentropic: $E = E(\alpha)$. (The results can easily be generalized to nonhomentropic fluids where $E = E(\alpha, S)$.) Consider variations $\delta \mathbf{a}(\mathbf{x}, t)$, of eqn [10], that leave the density and entropy unchanged. Then

$$\begin{aligned} \delta \int \mathcal{L} dt &= \iint dtd^3 \mathbf{a} \frac{\partial \mathbf{x}}{\partial t} \cdot \frac{\partial \delta \mathbf{x}}{\partial t} \\ &= - \iint dtd^3 \mathbf{a} \mathbf{A} \cdot \frac{\partial (\delta \mathbf{a})}{\partial t} \end{aligned} \quad [12]$$

where

$$\mathbf{A} = u\nabla_{\mathbf{a}}x + v\nabla_{\mathbf{a}}y + w\nabla_{\mathbf{a}}z \quad [13]$$

$\nabla_{\mathbf{a}}$ is the gradient operator in particle-label space, and we used the chain rule for partial derivatives to go from the second term to the third term in eqn [12]. After integration by parts, noting that $\delta\mathbf{a}(\mathbf{x},t)$ is arbitrary, one can show that

$$\partial/\partial t[(\nabla_{\mathbf{a}} \times \mathbf{A})] = 0 \quad [14]$$

Equation [14] is a general statement of vorticity conservation. Let $\theta(\mathbf{a})$ be any quantity that is conserved on fluid particles. Then

$$\partial/\partial t[(\nabla_{\mathbf{a}} \times \mathbf{A}) \cdot \nabla_{\mathbf{a}}\theta] = 0 \quad [15]$$

Using eqns [4] and [13] we have

$$(\nabla_{\mathbf{a}} \times \mathbf{A}) \cdot \nabla_{\mathbf{a}}\theta = \alpha(\nabla \times \mathbf{v}) \cdot \nabla\theta \quad [16]$$

and, from eqns [15] and [16], the statement

$$\partial/\partial t[\alpha(\nabla \times \mathbf{v}) \cdot \nabla\theta] = 0 \quad [17]$$

expresses the conservation of potential vorticity – *Ertel's theorem*.

Now consider any closed loop in $\mathbf{a}$ -space. By eqn [14], it follows that

$$\partial/\partial t \oint \mathbf{A} \cdot d\mathbf{a} = 0 \quad [18]$$

But $\mathbf{A} \cdot d\mathbf{a} = \mathbf{v} \cdot d\mathbf{x}$ by eqn [13], and the statement

$$\partial/\partial t \oint \mathbf{v} \cdot d\mathbf{x} = 0 \quad [19]$$

is *Kelvin's theorem*.

It should be noted that commuting the time derivative and the contour integral is a nontrivial matter in the Eulerian setting (see Betounes, 1983, and compare with Lamb, 1932).

Reduction of Order

The state of a perfect fluid at a fixed time t corresponds to a point in an infinite-dimensional phase space in which each dimension represents the value of one component of $\mathbf{v}(\mathbf{a})$ or $\mathbf{x}(\mathbf{a})$ at a fixed value of $\mathbf{a}$. The six Lagrangian fields

$$\{\mathbf{v}(\mathbf{a}), \mathbf{x}(\mathbf{a})\}$$

uniquely determine the five Eulerian fields

$$\{\mathbf{v}(\mathbf{x}), \rho(\mathbf{x}), S(\mathbf{x})\}.$$

However, each choice of $\{\mathbf{v}(\mathbf{x}), \rho(\mathbf{x}), S(\mathbf{x})\}$ corresponds to infinitely many choices of $\{\mathbf{v}(\mathbf{a}), \mathbf{x}(\mathbf{a})\}$. Thus the Eulerian description is a *reduced phase space* for the fluid. A group-theoretic picture of the reduction from Lagrangian to Eulerian variables gives a more rigorous description, but this fundamental topic is a subject for further reading.

Numerical Techniques

Lagrangian thinking manifests itself in the design of numerical methods. Here we give a brief review of two schemes: semi-Lagrangian techniques, which are widely used and a novel Lagrangian approach to the semigeostrophic frontogenesis model – the so-called geometric method.

Semi-Lagrangian Schemes

Semi-Lagrangian schemes are important because they offer the promise of allowing longer time steps, with no loss of accuracy, than Eulerian-based advection schemes whose time step is limited by stability criteria. These issues are of practical importance in numerical weather prediction.

To illustrate the essential ideas, let us consider a simple one-dimensional advection equation in Eulerian form

$$\frac{\partial A}{\partial t} + u \frac{\partial A}{\partial x} = 0 \quad [20]$$

where $A(x,t)$ is the transported quantity. The appropriate Lagrangian form of eqn [20] is the pair of equations

$$\frac{dA}{dt} = 0 \quad [21a]$$

$$\frac{dx}{dt} = u \quad [21b]$$

Equation [21a], states that A is conserved along the trajectory, which is in turn given by the eqn [21b]. We seek to integrate eqn [21a] and [21b] by gridpoint techniques. (This is the origin of the term ‘semi’ in semi-Lagrangian – the combination of Lagrangian mechanics with Eulerian gridpoint techniques.) Let Δt denote a time step and let n label the time steps. For each point on the grid we approximate the trajectory that would arrive at that point at time $(n+1)\Delta t$ using the wind u at time n . We refer to the point at which the forecast is made as the arrival point (A) and the point from which the trajectory departed at time $(n-1)\Delta t$ as the departure point (D). The point in the middle of the trajectory at time $n\Delta t$ is called the midpoint (M). The departure point is determined by approximating eqn [21b] with

$$\frac{x_D - x_A}{-2\Delta t} = u(x_M) \quad [22]$$

The midpoint, at which u is needed in eqn [22], is obtained by a similar expression

$$\frac{x_M - x_A}{-\Delta t} = u(x_M) \quad [23]$$

which is implicit since u at x_M cannot be determined until x_M is known. This requires an iterative process in which the next guess of x_M on the left is based on u at x_M from the previous iteration. Once x_M is found, the departure point calculated from eqns [22] and [21a] yields

$$A(x_A)^{n+1} = A(x_D)^{n-1} \quad [24]$$

Typically the departure points and midpoints will not coincide with grid points. The values of A and u at these points must be found by interpolation from neighboring points and the scheme is stable provided the interpolation is based on data points surrounding the departure point (or midpoint). There is essentially no time step restriction and thus, near the poles of a global model where grid lines converge, the departure point may be many grid intervals away from the arrival point without being unstable.

Geometric Method

The geometric method was born out of an attempt to demonstrate the value of a Lagrangian approach to

Figure 1 (a) Projection of a polyhedral surface $P(x, z)$ onto the (x, z) -plane. The front is modeled as a discontinuity in the gradients of the faces that make up the piecewise planar surface. (b) Construction of a convex polyhedral surface $P(x, z)$ from faces with given gradients $(\theta_i M_i)$ and areas.

understanding the dynamics of rotating, stratified fluids. It is a novel technique for integrating the semigeostrophic equations that involves dividing the atmospheric domain into elements, each characterized by a certain mass, potential temperature, and absolute momentum. Applications of the geometric method include modeling frontogenesis, embedded convection, sea breezes, and flow over orography. Some of the advantages of the geometric method include the ability to handle a frontal discontinuity, no eddy diffusion requirement and, in principle at least, mountain barrier effects (e.g., drag) can be represented without parameterization. An example of a ‘tropopause fold,’ constructed via the geometric method with 10^5 elements, is illustrated in Figure 1(a).

The geometric method may be summarized as follows. Consider a domain D with coordinates (x, y, z) , taken to represent a region of the Northern Hemisphere (y pointing poleward). Let C be a cross section

$$C = \{(x, z) : -L \leq x \leq L, 0 \leq z \leq H\}$$

(where typical values of L and H may be 1000 and 10 km, respectively). The geometric method discretizes the fluid in C into ‘parcels’ of equal area C_i , so that $C = \sum_i C_i$. To the i th parcel is associated a value of ‘absolute momentum’ $M_i = (v_g + fx)_i$ and a value of potential temperature θ_i . Here, v_g is the y -component of the geostrophic wind, $v_g = (1/f)\partial\phi/\partial x$, $\phi(x, z)$ is the geopotential function, and f is the constant Coriolis parameter. One can show that a convectively and inertially stable arrangement of the fluid parcels can be represented uniquely by a convex function $P(x, z) = \frac{1}{2}f^2x^2 + \phi$ (sometimes referred to as the ‘modified geopotential’ or ‘modified pressure’), such that each element C_i can be associated with a plane whose height ‘above’ the (x, z) -plane at any point corresponds to the value of P at that point. The intersection of these planes defines a piecewise planar solution $P(x, z)$ (Figure 1(b)). The momentum of each parcel, M_i , and potential temperature of each parcel, θ_i , are proportional to the gradients of $P(x, z)$ with respect to x_i and z_i , respectively.

The constraint that P be a convex function is crucial to the solution procedure. It allows us to write the physical solution as the supremum of a family of generating surfaces

$$P(x, z) = \max_i \{xM_i + z\theta_i + S_i\} = \max P_i$$

where P_i denotes the modified pressure plane of the i th element and S_i the point of intersection on the P -axis of a plane in (x, z, P) -space. In a physical problem involving time integration, we begin with a set of values C_i , M_i , θ_i , and S_i . The construction algorithm requires the determination of the set of S_i values such that the element areas are correct – a process that must be carried out iteratively. If the domain boundary is fixed or a known function of time, one may regard S_i as a function of C_i , M_i , and θ_i . In the classical frontogenesis problem where a pure barotropic deformation field is imposed, the governing Lagrangian equations take the form

$$\frac{DM_i}{Dt} = -\eta M_i, \quad \frac{DC_i}{Dt} = -\eta C_i, \quad \frac{D\theta_i}{Dt} = F_i \quad [25]$$

where η is the deformation rate and F_i is a forcing function (which is zero in the frontogenesis problem under consideration). Therefore, at any future time C_i , M_i , and θ_i are known and the solution can be found by determining S_i .

Lagrangian Analysis

The description of weather systems and ocean eddies has always utilized the Lagrangian description of the flow. Examples include synoptic developments in terms of air masses (dating back to the Bergen School in the early twentieth century), the parcel theory of convection, and the description of the dynamics of precipitation systems in terms of conveyor belts. The power of the Lagrangian description in these contexts is the conceptual simplification achieved by burying the nonlinearity of the material derivative D/Dt in the Jacobian of the map between particle labels and Lagrangian positions: $\alpha = \partial(\mathbf{x})/\partial(\mathbf{a})$ (cf. eqn [4]). However, whenever we wish to carry out a theoretical analysis of hydrodynamical flows, the Eulerian framework is the most commonly used vehicle. In this section we give a brief resumé of a Lagrangian method of analysis that, although hitherto not widely used, offers a powerful technique for analyzing, for example, the conceptually simple (yet analytically difficult in the Eulerian setting) problems of transportation along particle trajectories.

Atmospheric Dynamics and Rearrangements

A concept that arises naturally when considering the Lagrangian description of fluid motion is that of the rearrangement of the fluid by the material derivative. The action of the D/Dt operator on an arbitrary quantity A is to advect, or rearrange, it. Consider for example a conserved quantity, such as potential vorticity $q = \rho^{-1}\zeta \cdot \nabla\theta$, that retains its value following a fluid particle. Here, ρ is the fluid density, θ the potential temperature, and ζ the total vorticity. As time advances the fluid particles are permuted or rearranged, but each particle retains its original value of q .

Atmospheric cyclones and anticyclones, and ocean eddies, can be idealized as the stratified, rotating coherent structures

that correspond to circular vortices in ordinary two-dimensional Euler flow. Their interaction and evolution, which play a major role in weather developments and in the behavior of ocean eddies, have been much studied using approximations to Newton's second law of motion. These approximate models seek to describe flows in which there is a dominant balance between the Coriolis, buoyancy, and pressure-gradient forces. Such approximations to Newton's second law are commonly referred to as *balanced models*. Many such models can be described in terms of the Lagrangian conservation of potential vorticity by an equation

$$\frac{Dq}{Dt} = 0$$

together with a so-called invertibility principle

$$E(\mathbf{v}, \theta, p) = q \quad [26]$$

that relates the wind field $\mathbf{v}$, pressure p , and potential temperature θ to the potential vorticity. Typically, E will be an elliptic operator, which may be nonlinear, and certain boundary conditions must be specified. A relationship between the wind, temperature, and pressure fields is known as a balance condition, which is required to define the relationships implicit in eqn [26]. Examples of models that can be formulated in this way are the barotropic vorticity equation, quasi-geostrophic theory, and semigeostrophic theory. The solutions to all these models can be described as rearrangements of the initial potential vorticity distribution, and because the advecting velocity is constrained by the invertibility procedure, progress in understanding features such as existence and uniqueness and the topological properties of solutions can be made because the elliptic operator governs the type of rearrangement that can be reached from the given initial data.

The precise definitions of a rearrangement of functions (both scalar-valued and vector-valued) require concepts from measure theory, and as such have very precise technical definitions. However, the technical nature of the definitions is extremely important, since it gives a firm basis to the mathematical analysis. Bearing this in mind, we will give an intuitive definition. Consider a region, D , spanned by the coordinates (x, y, z) and let $f(\mathbf{x})$ be a function defined on this region (e.g., moisture or potential vorticity). Within the region we have our fluid with Lagrangian coordinates $(\mathbf{a}, t)$ and let us assume we can attach values of the function f to each fluid particle, thereby giving us a function $F(\mathbf{x}, t_0)$, at some reference time t_0 . As the state of the fluid evolves according to a dynamical model, at a later time t_1 we have a new function $G(\mathbf{x}, t_1)$, which we call a rearrangement of F if the two functions satisfy a certain equivalence relationship between the 'sizes' or 'volumes' of the sets on which F and G take values greater than or equal to a datum value, for all real positive datum values. An example of two functions F and G that are rearrangements according to this definition is given in Figure 2.

Possible applications of rearrangements include numerical methods in which the goal is to model the evolution of a quantity such as potential vorticity as accurately as possible. In variational data assimilation it may be useful to work with Lagrangian increments, instead of Eulerian perturbations, in which minimization is carried out over certain classes of 'dynamically accessible' rearrangements. Rearrangements can

Figure 2 Two rearrangements F and G ; the area of the shaded regions is the same for every value of the datum point α .

be used to compare two functions of spatial variables and as such there may be applications in the future to forecast verification techniques.

A significant achievement of rearrangement theory to date is its application to the study of the stability of steady states. Steady states can be characterized as stationary points of the energy with respect to rearrangement perturbations, which is not possible if Eulerian perturbations are used.

Synopsis

The significance of the potential vorticity (PV) for atmosphere–ocean dynamics was first explored by Carl-Gustaf Rossby in the 1930s. Reviewed here are its key properties including invertibility, material invariance, and the impermeability theorem – the last two suggesting mixability along stratification surfaces. These properties easily explain the once-mysterious antifriction or ‘negative viscosity’ of strongly nonlinear atmosphere–ocean eddy fields, outside the scope of linear theory and homogeneous turbulence theory. Invertibility implies that eddy fluxes of momentum are intimately related to isentropic eddy fluxes of PV, including those due to strongly nonlinear disturbances, as summarized by the quasigeostrophic Taylor identity.

The Fundamental Definition

The idea of the potential vorticity (PV) as a material invariant central to stratified, rotating fluid dynamics was first introduced and explored by Carl-Gustaf Rossby in the 1930s. Material invariance means constancy on a fluid particle. The PV, a scalar field, will be denoted here by P and can be defined in several ways, as shown shortly. We have

$$DP/Dt = 0 \quad [1]$$

for dissipationless flow, where D/Dt is the material derivative. For such flow we also have material invariance of the potential temperature θ ,

$$D\theta/Dt = 0. \quad [2]$$

Rossby’s idea, as it originally emerged from his papers of 1936, 1938, and 1940, was to introduce a vorticity-like quantity that is related to the vertical component of vorticity in the same way that potential temperature is related to temperature. In his 1938 and 1940 papers he recognized, moreover, that ‘vertical’ can more accurately be replaced by ‘normal to stratification surfaces,’ i.e., in the atmosphere, normal to isentropic or constant- θ surfaces.

Equivalent to this is the idea, clearly emerging on page 252 of the 1938 paper, that P is exactly proportional to the absolute Kelvin circulation C_Γ , eqn [7] below, around an infinitesimally small closed material contour Γ lying on an isentropic surface. The exact material-invariance property [1] is then obvious from Kelvin’s circulation theorem, as generalized by V. Bjerknes, since [2] ensures that the material contour Γ remains on the isentropic surface.

Rossby’s idea is today recognized as having central and far-reaching importance for understanding the dynamical behavior not only of planetary atmospheres and oceans but also of the radiative interiors of solar-type stars. It is especially important for understanding *balanced flow* and thence a vast range of basic dynamical processes, such as Rossby-wave propagation and breaking and its many consequences including, in the Earth’s atmosphere, global-scale teleconnections, antifrictional phenomena such as jet stream self-sharpening, and the genesis of cyclones, anticyclones and storm tracks, answering the child’s age-old question of where the wind comes from.

The relation $P \propto C_\Gamma$ provides the simplest and most fundamental way to define P exactly, not only for continuously

stratified systems but also for single-layer shallow-water or ‘equivalent barotropic’ models and their multilayer extensions. For continuous stratification, today’s standard definition of P chooses the constant of proportionality to be $d\theta$, the potential-temperature increment between a pair of neighboring isentropic surfaces (see Figure 1), divided by the mass of the small material fluid element lying between those surfaces and having perimeter Γ . Mass conservation is assumed throughout this article.

For the single-layer and multilayer models, one needs only to replace the pair of isentropic surfaces by layer boundaries. Then for finite layer thickness the proportionality constant can be chosen as simply the reciprocal of the mass of the material element, or of its volume when the usual incompressible-flow assumption is made. Then from Stokes’ theorem P becomes absolute vorticity divided by layer thickness, the formula first presented in Rossby’s 1936 paper.

For continuous stratification, Rossby derived an approximate formula adequate for use with synoptic-scale observational data. With the foregoing choice of proportionality constant, Rossby’s formula is

$$P \approx g \left\{ \left(\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} \right)_\theta + f \right\} \left| \frac{\partial \theta}{\partial p} \right| \quad [3]$$

where g is the gravitational acceleration, p is pressure, and f is the Coriolis parameter, a function of latitude. To obtain [3] from the exact relation $P \propto C_\Gamma$ one must assume that the mass and pressure fields are related hydrostatically and that the slopes of isentropic surfaces are small in comparison with unity. In practice these conditions usually hold to more than

Figure 1 Sketch showing the material mass element defined by a small isentropic contour Γ and a pair of neighboring isentropic (stratification) surfaces with potential temperatures θ and $\theta + d\theta$. The exact PV is the mass-normalized Kelvin circulation around Γ , in the limit of an infinitesimally small element (see text). In a layer model, the two surfaces are taken instead as the layer boundaries.

sufficient accuracy. The horizontal coordinates x, y in [3] are local Cartesian coordinates in a tangent-plane representation, with corresponding horizontal velocity components u, v relative to the Earth. The formula converts to spherical or other coordinates in the same way as the ordinary vertical vorticity.

However, as Rossby pointed out, the quantity within braces is not the ordinary vertical vorticity. The subscript θ is crucial. It signifies that the horizontal differentiations of the horizontal velocity components are to be carried out with θ held constant. That is, one stays on a single isentropic surface, just as one does when calculating C_T . Rossby explains this point very clearly on, for instance, page 253 of his 1938 paper. The resulting quantity, bearing a superficial resemblance to the ordinary vertical vorticity, can more aptly be called Rossby's *isentropic vorticity*. Within the approximations involved in [3], this isentropic vorticity is the same as the component of the vorticity vector normal to the isentropic surface. It can differ substantially from the vertical vorticity.

Such differences are commonplace in balanced flows with strong vertical shear ($\partial u/\partial z, \partial v/\partial z$), where z is geometric altitude or pressure altitude. That is, they are commonplace in balanced flows with high baroclinicity. Examples include tropopause jet streams. Baroclinicity means tilting of isentropic surfaces relative to isobaric surfaces, usually the cross-stream tilting that balances the vertical shear as indicated by the so-called thermal wind equation. A natural measure of baroclinicity is $1/Ri$, where $Ri = N^2/(\partial|\mathbf{u}|/\partial z)^2$, the gradient Richardson number, where $N^2 = g\theta^{-1}\partial\theta/\partial z$, the square of the buoyancy frequency. The shear and cross-stream tilting effects were shown to make substantial contributions to the right-hand side of [3] in, for instance, the 1950s work of R. J. Reed, F. Sanders, and E. F. Danielsen on observational data describing tropopause fronts and jet streams, in which air of stratospheric origin was recognized by its relatively high values of P . Slopes are geometrically small but Ri values low enough for the subscript θ to be important in [3].

Equations [1]–[3] provide a remarkably succinct description of how dissipationless processes affect the component of absolute vorticity normal to an isentropic surface. There are two distinct effects. The first is that the normal component of absolute vorticity increases through vortex stretching if the isentropic surfaces move apart. This is a generalization of angular momentum conservation, i.e., a generalization of the ballerina effect or ice-skater's spin. The second is that the normal component of absolute vorticity is preserved if the isentropic surfaces do nothing but tilt away from the horizontal.

The generalized ballerina effect often contributes to the spin-up of cyclonic vortices, such as the small vortex over the Balkans in Figure 2. The colors mark air with different estimated values of P , on the $\theta = 320$ K isentropic surface at geometric altitudes around 10 km, with the warmest colors marking the highest P values. The vortex over the Balkans has a core of high- P air that has undergone stretching, while moving equatorward out of the stratosphere. The cyclonic, i.e., counterclockwise, rotation of the core relative to the surrounding air shows up as a tendency of the surrounding colored filaments to be wound up into spirals.

The estimated isentropic distribution of P shown in Figure 2 was derived from an initial coarse-grain estimate from operational weather-forecasting analyses together with an assumption that material invariance, [1] with [2], holds to sufficient accuracy over 4 days. A highly accurate tracer advection technique, contour advection, was used. It was first introduced into the atmospheric-science literature by W. A. Norton, R. A. Plumb and D. W. Waugh following work of N. J. Zabusky and D. G. Dritschel. The pattern thus revealed, reminiscent of cream on coffee, illustrates the typical advective effects of the layerwise-two-dimensional flow characteristic of mesoscale and larger-scale flow regimes heavily constrained by stable stratification. Such regimes can often be considered to be balanced flows, whose isentropic distributions of P contain nearly all the

Figure 2 Estimated isentropic distribution of the (Rossby–Ertel) PV on the 320 K isentropic surface on 14 May 1992 at 1200 UT (Greenwich mean time), derived from observations as explained in the text. Over Europe the 320 K surface lies near jetliner cruising altitudes $z \sim 10$ km. The estimate used data from the operational weather-prediction analyses of the European Centre for Medium Range Weather Forecasts (ECMWF). Values from 1 PVU upwards are colored rainbow-wise from dark blue to red, with contour interval 1 PVU, where $1 \text{ PVU} = 10^{-6} \text{ m}^2 \text{ s}^{-1} \text{ K kg}^{-1}$. Courtesy W. A. Norton (personal communication); further details in Appenzeller et al. (1996). Figure 15(b) on p. 1450 of that paper checks that the wind field does, as expected from PV inversion, exhibit the usual tropopause jet structure around the periphery of the large high-PV region on the left. See *PV Mixability and Strong Jets* below.

information about the dynamics. This will be made precise in the section on [PV Inversion](#).

Ertel's Formula

For continuous stratification it is a simple exercise in vector calculus to show, via Stokes' theorem, that Rossby's fundamental relation $P \propto C_\Gamma$ is exactly equivalent to

$$P = \rho^{-1} \zeta^a \cdot \nabla \theta \quad [4]$$

when the constant of proportionality is chosen as before. Here ρ is the mass density, ∇ is the three-dimensional gradient operator, and ζ^a is the absolute vorticity vector, the curl of the three-dimensional velocity field viewed in an inertial frame. In the Earth's rotating frame, ζ^a is the three-dimensional relative vorticity added vectorially to twice the Earth's angular velocity vector $\mathbf{\Omega}$. The formula [4] was first published in 1942 by Hans Ertel, who had visited Rossby at MIT in 1937. The formula has attracted much attention in the mathematical fluid-dynamics community and has been generalized in various ways.

In strongly stratified flows like that of [Figure 2](#) we have $N^2 \gg 4|\mathbf{\Omega}|^2$. Also, the small-slope approximation is valid, making $\nabla \theta$ nearly vertical. In [4], the scalar multiplication by $\nabla \theta$ picks out f , the latitude-dependent vertical component of $2\mathbf{\Omega}$, to good approximation. This is the fundamental reason why f and its latitudinal variation often suffice to capture the main effects of the Earth's rotation $\mathbf{\Omega}$, including the so-called beta effect.

Under the small-slope and hydrostatic approximations, $\rho^{-1}|\nabla \theta|$ is approximately equal to $g|\partial \theta / \partial p|$ in [3]. The contributions to [3] and [4] from $2\mathbf{\Omega}$ therefore agree. It is straightforward to show that the remaining contributions also agree in these circumstances provided that, for consistency with the hydrostatic approximation, the vertical component of velocity is neglected when taking the curl of the relative velocity field to form the relative vorticity.

The small-slope and hydrostatic approximations are usually so good that [3] and [4] give practically indistinguishable results when evaluated from typical meteorological datasets, and from the output of numerical weather-forecasting models. So [3] and [4] are often treated as equivalent for practical purposes, both being called 'exact' when distinguishing them from the much less accurate formulae for the material invariants possessed by certain approximate balanced models, such as quasigeostrophic theory and semigeostrophic theory. Their material invariants are also called potential vorticities but are defined by formulae that differ substantially from [3] and [4], for instance [15]. Unlike [3] and [4] these formulae cannot be considered quantitatively accurate. The PV in its quantitatively accurate sense will be referred to as the *Rossby–Ertel potential vorticity* or simply, for brevity, the PV, whether defined by [3] or [4] or by any other formula accurately equivalent to $P \propto C_\Gamma$.

To check that [4] is accurately, indeed exactly, equivalent to $P \propto C_\Gamma$ and materially invariant for dissipationless flow, we note first that [4] can be rewritten exactly as

$$P = \sigma^{-1} \zeta^a \cdot \mathbf{n} \quad [5]$$

where $\sigma = \rho/|\nabla \theta|$, and $\mathbf{n} = \nabla \theta / |\nabla \theta|$, the upward-directed unit normal to the isentropic surface $\mathcal{S}$, say, on which P is being

evaluated. The scalar field σ , a stratification-related mass density, is a strictly positive quantity. Under the small-slope approximation it is the mass density in isentropic coordinates. With the definition just given, $\sigma d\theta$ is exactly the mass per unit area between neighboring isentropic surfaces, such as those sketched in [Figure 1](#), whose θ values differ by $d\theta$. Thus if dA is the area element of integration on the surface $\mathcal{S}$, then $\sigma dA d\theta$ is exactly the mass element of integration.

For dissipationless flow we have [2] as well as mass conservation, hence

$$\int_{\mathcal{S}(\Gamma)} \sigma dA = \text{constant} \quad [6]$$

where $\mathcal{S}(\Gamma)$ denotes any simply connected portion of $\mathcal{S}$ enclosed by a material contour Γ . Here Γ can, but need not, be small. By definition its Kelvin circulation is

$$C_\Gamma = \oint_{\Gamma} \mathbf{u}^a \cdot d\mathbf{x} = \text{constant} \quad [7]$$

for dissipationless flow, where $\mathbf{u}^a$ is the three-dimensional velocity field in the inertial frame. From Stokes' theorem and [5] we have exactly

$$C_\Gamma = \int_{\mathcal{S}(\Gamma)} \zeta^a \cdot \mathbf{n} dA = \int_{\mathcal{S}(\Gamma)} P \sigma dA \quad [8]$$

and if, as before, we now take Γ to be small – more precisely, if we take the greatest diameter of Γ to be arbitrarily small in comparison with all lengthscales of the flow – then P is simply [8] divided by [6]. This verifies not only the material invariance of P but also the equivalence of [4] and [5] to $P \propto C_\Gamma$ for small Γ , with the choice of proportionality constant made earlier.

For completeness we sketch the alternative derivation given by Ertel, written using the three-dimensional velocity field $\mathbf{u}$ relative to the rotating frame. One takes the scalar product of $\nabla \theta$ with the frictionless three-dimensional vorticity equation, the curl of the nonhydrostatic equation for $D\mathbf{u}/Dt$, and then makes use of $\nabla(D\theta/Dt) = 0$ from [2]. Note that $D/Dt = \partial/\partial t + \mathbf{u} \cdot \nabla$ and that the three-dimensional gradient operator ∇ acts on $\mathbf{u}$ as well as on θ . The baroclinic term in the vorticity equation, proportional to $\nabla p \times \nabla \rho$, is annihilated when the scalar product with $\nabla \theta$ is taken, because the thermodynamics says that θ is a function of p and ρ alone (the standard approximation to this function implying that $\theta \propto T/p^\kappa$, $\kappa \approx 2/7 \approx 0.286$, with temperature $T \propto p/\rho$). The result is a conservation relation in the general sense of the term, in 'flux form,'

$$\frac{\partial}{\partial t}(\rho P) + \nabla \cdot (\rho \mathbf{u} P) = 0 \quad [9]$$

with P defined by [4] or [5]. Putting this together with the corresponding equation

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{u}) = 0 \quad [10]$$

expressing mass conservation, we immediately obtain eqn [1] for dissipationless flow.

A corollary of material invariance and mass conservation is the existence of so-called Casimir invariants. They are important in theories that make explicit the Hamiltonian mathematical structure of the dissipationless dynamics, and in associated

theorems on instability and on wave–mean interaction. Note first that we have not only constancy of [8] but also

$$\iint_{\mathcal{S}(\Gamma)} \varphi_1(P) \sigma dA = \text{constant} \quad [11]$$

where $\varphi_1(P)$ is an arbitrary function and Γ is again arbitrary. This is because each mass element has a single value of P and therefore a single value of $\varphi_1(P)$. Extending $\mathcal{S}(\Gamma)$ to span the whole fluid domain and integrating over all surfaces $\mathcal{S}$, with arbitrary θ -weighting, we obtain

$$\iiint \varphi_2(P, \theta) \sigma dA d\theta = \text{constant} \quad [12]$$

with $\varphi_2(P, \theta)$ another arbitrary function, where the integral is taken over the whole fluid domain. These domain integrals [12] are the Casimir invariants. They are exactly constant for any dissipationless flow whatever.

PV Units and the Extratropical Tropopause

Rossby's original choice of proportionality constant differed from today's standard choice. As noted in his 1940 paper, Rossby chose the physical dimensions of P to be the same as those of ordinary vorticity, namely $(\text{time})^{-1}$ drawing on the analogy with potential temperature. (See text between his eqns [11] and [13].) However, the usual practice today is to tolerate the slightly looser analogy and different physical units implied by [3]–[5], for the sake of having simpler formulae. The standard PV unit used today is $10^{-6} \text{ m}^2 \text{ s}^{-1} \text{ K kg}^{-1}$, abbreviated PVU.

By a strange accident, cross-sections of the atmosphere show P values typically around 2 PVU at the extratropical tropopause, and this has proved extremely useful as a way of defining the tropopause outside a tropical band of latitudes, say outside $\pm 20^\circ$ or so. More precisely, the extratropical tropopause is often marked by steep isentropic gradients of P with values ranging from about 1 to 4 PVU. The shape of the 2-PVU contour in Figure 2, dividing dark blue from light blue, gives no more than a slight hint of the complicated three-dimensional shape of the tropopause, where it intersects the 320 K isentropic surface at the instant shown. The instantaneous tropopause is a highly convoluted surface with an overall poleward–downward slope, so that the white areas in Figure 2 are in the troposphere and the main colored areas are in the stratosphere.

Airborne measuring instruments flown along the 320 K surface and crossing from white through dark blue into light blue and warmer-colored areas would see changes in chemical composition characteristic of the transition from tropospheric to stratospheric air. Indeed, such changes have often been observed in association with finer-scale, filamentary structures of the kind seen in the figure, beginning with the pioneering work of D. W. Waugh and R. A. Plumb in the early 1990s using chemical data from NASA's ER-2 aircraft.

The usefulness of the PV as an extratropical tropopause marker is an accident because, for one thing, it depends on the choice of θ as the thermodynamical material invariant that satisfies [2] and appears in the definitions [3]–[5]. There is no fundamental reason for that choice. Everything in the dynamical theory works just as well with other thermodynamical material

invariants such as the specific entropy, or indeed any other smooth, monotonic function of θ . The PV thus redefined is sometimes called a *modified PV*. Isentropic distributions of P like that in Figure 2 remain the same after such modification, apart from changes to the units and to the numerical values assigned to each color. Notice, however, that the normalizing factors for those changes depend on θ and are therefore different on each isentropic surface.

PV Inversion and Generalized PV

Any flow that can be considered balanced whether geostrophically or at higher accuracy (see **Dynamical Meteorology: Balanced Flow**) satisfies what is now called the *invertibility principle* for PV. The principle says that, to an accuracy limited only by the accuracy of the balance relation, one can capture all the dynamical information about the flow by specifying only the following:

1. the mass under each isentropic surface $\mathcal{S}$,
2. the isentropic distributions of P , on all the surfaces $\mathcal{S}$, and
3. the distributions of θ on the lower boundary and on the upper boundary if present.

By implication there exists, then, a nonlocal diagnostic operator, the *PV inversion operator* associated with the given balance relation. Its input is the foregoing information at some instant. Its output is the remaining dynamical information at the same instant including the p , ρ , T , and $\mathbf{u}$ fields. Very often $\mathbf{u}$ is dominated by its horizontal component, the weaker vertical component nevertheless being dynamically significant thanks to its role in the generalized ballerina effect, and in moving and tilting isentropic surfaces.

The idea of PV inversion is implicit in textbook descriptions of, for instance, the Rossby-wave mechanism. The idea is used at the point in the argument where the horizontal component of $\mathbf{u}$ is deduced diagnostically from the disturbance PV field associated with PV-contour undulations. Sometimes the term *induced velocity*, borrowed from aerodynamics, is used. In this context it means the velocity field deduced from the PV field by inversion.

What are PV inversion operators like, qualitatively? A partial answer is that calculating the horizontal component of $\mathbf{u}$ is like calculating the electric field $\mathbf{E}$ induced by a certain electric-charge distribution, and then taking the horizontal component of $\mathbf{E}$ and rotating it counterclockwise through a right angle, for instance from northward to westward. The electric charges correspond to isentropic anomalies in P and boundary anomalies in θ . Thus, for instance, the positive isentropic anomaly in P over the Balkans in Figure 2 corresponds to a positive electric charge, inducing an outward-pointing $\mathbf{E}$ field and hence a cyclonic or counterclockwise velocity field around it. This provides us with a way of saying what the terms vortex, cyclone, and anticyclone really mean. For instance the vortex over the Balkans, an upper-air cyclone, is nothing but a positive isentropic anomaly in P together with its induced velocity field.

Because of the balance relation, these velocity fields are accompanied by p , ρ , and T fields that to a first approximation satisfy the thermal wind equation; for instance the upper-air cyclone has a warm T anomaly above it and a cold T anomaly beneath. Conversely, an upper-air anticyclone has a cold T

anomaly above, a fact crucial to lower-stratospheric polar ozone chemistry. Flow through such a cold anomaly cannot advect the negative PV anomaly beneath, but can give rise to fast cloud formation and accelerated chemical processing.

Similar statements about vortices apply to the distributions of θ at, say, the lower boundary surface. (In practical terms, taking friction into account, this translates to 'just above the planetary boundary layer.')

A surface cyclone or *heat low* is nothing but a positive, i.e., warm, lower boundary anomaly in θ together with its induced velocity field, and conversely for a surface anticyclone.

Severe cyclonic storms in the extratropical atmosphere often arise from the vertical alignment of warm lower boundary anomalies in θ and positive upper-air isentropic anomalies in P like the large cyclonic anomaly seen on the left of [Figure 2](#). Helped by such vertical alignment, the induced velocities can add up to give storm-force winds. Furthermore, the development of such a situation by upper-air positive- P advection along with near-surface warm advection, and poleward upgliding along sloping isentropes, induces large-scale upward motion. Such upward motion is described by any sufficiently accurate PV inversion operator. Alternatively, it can be computed via the so-called omega equation. The large-scale upward motion may trigger latent heat release, creating or intensifying isentropic anomalies in P . Especially in moist air over the extratropical oceans, the upshot can be the sudden explosive marine cyclogenesis feared and respected by sailors: "Three days from land a great tempest arose..."

It hardly needs saying that, whenever the invertibility principle holds to sufficient accuracy, it gives us a vastly simplified conceptual view of the dynamical evolution. The dynamical system is completely specified by a PV inversion operator together with the remarkably simple prognostic equations [\[1\]](#) and [\[2\]](#) or their diabatic, frictional generalizations. Those equations provide us with the simplest way to cope with the bedrock mathematical difficulty of fluid dynamics, the advective nonlinearity.

Since P and θ are scalar fields, keeping track of them using pictures like [Figure 2](#), actual or mental, is a far simpler task than keeping track of the evolving p , ρ , T , and $\mathbf{u}$ fields in three dimensions, including the nonlocal effects mediated by the p field under the constraints imposed by the balance relation. The nonlocal effects are all encapsulated in the PV inversion operator. The foregoing points, implicit in Rossby's work, were articulated with increasing clarity by Jule G. Charney and Aleksandr M. Obukhov in the late 1940s and by Ernst Kleinschmidt in the early 1950s. They allow us to make sense not only of Rossby-wave propagation, cyclogenesis, and anticyclogenesis but also, for instance, of aerodynamical ideas like vortex rollup – the idea that a strong isentropic anomaly in PV can roll 'itself' up into a nearly circular vortex, as in the Balkans example of [Figure 2](#).

In 1966 Francis P. Bretherton pointed out that an even greater conceptual simplification is possible. The single prognostic equation [\[1\]](#) is enough to determine the dissipationless evolution by itself, provided that we consider the PV field $P(\mathbf{x}, t)$ to contain delta-function contributions at the upper and lower boundaries, with strengths determined by the θ distributions at the boundaries. Ignoring frictional boundary-layer phenomena, we may relate this to the idea that isentropic

surfaces $\mathcal{S}$ intersecting the lower boundary, say, can be imagined to continue along the boundary in an infinitesimally thin layer of infinite $|\nabla\theta|$ hence infinite P . In the electrostatic analogy, surface θ distributions correspond to surface charge distributions – electric charge per unit area rather than per unit volume. The PV field with surface θ distributions included may be called the *generalized PV field*, containing all the information in the second and third numbered items above.

Some Illustrations

The idea of PV inversion can be illustrated in a simple way by considering the theoretical limiting case of infinite sound speed and infinite stable stratification. The buoyancy frequency N and gradient Richardson number both tend to infinity. The isentropic surfaces $\mathcal{S}$ become rigid and horizontal – horizontal in the billiard-table sense, with the sum of the gravitational and centrifugal potentials constant. The balance relation degenerates to a statement that the flow on each $\mathcal{S}$ is strictly horizontal and strictly incompressible. Then, in the rotating frame, we have $\mathbf{u} = \hat{\mathbf{z}} \times \nabla_H \psi$ for some streamfunction ψ , where $\hat{\mathbf{z}}$ is a unit vertical vector, and, from [\[5\]](#),

$$P = \sigma^{-1}(f + \nabla_H^2 \psi) \quad [13]$$

with σ now strictly constant. Here ∇_H is the two-dimensional horizontal gradient operator and ∇_H^2 the corresponding Laplacian, so that $\nabla_H^2 \psi$ is the relative vorticity. We may regard [\[13\]](#) as a Poisson equation to be solved for ψ when P is given. Solving it is a well-defined, and well-behaved, operation, given suitable boundary conditions such that the P field on each $\mathcal{S}$ satisfies [\[8\]](#) with Γ taken as the horizontal domain boundary; see also [\[16\]](#). Symbolically, in the rotating frame,

$$\mathbf{u} = \hat{\mathbf{z}} \times \nabla_H \psi \text{ with } \psi = \nabla_H^{-2}(\sigma P - f) \quad [14]$$

expressing PV invertibility in the limiting case. The PV inversion problem now resembles an electrostatics problem in two, rather than three, dimensions. The charge distribution corresponds to σ times the PV anomaly $(P - \sigma^{-1}f)$, with $-\psi$ in the role of the electric potential. In this limiting case, as in general, PV inversion is a diagnostic, nonlocal operation.

Notice that our limiting case is degenerate in another sense as well. The altitude z now enters the problem only as a parameter. There is no derivative $\partial/\partial z$ anywhere in the problem, either in the horizontal Laplacian or in the material derivative $D/Dt = \partial/\partial t + \mathbf{u} \cdot \nabla$ in [\[1\]](#), with $\mathbf{u}$ strictly horizontal. Not only is the flow layerwise-two-dimensional, but the layers are completely decoupled from each other. For the validity of this picture there is, therefore, an implicit restriction on magnitudes of $\partial/\partial z$, i.e., an implicit restriction on the smallness of vertical scales in the limit, with the further implication that the picture cannot be uniformly valid for all time.
